Preface

By the time this weighty volume is published, more than 10 years will have passed since I first approached Taylor & Francis (formerly CRC Press) about this project. I was surprised and delighted when they agreed to undertake this second edition. In the preface to the first edition I told readers that “a tremendous amount” had been learned about the problem of drug abuse, and I observed that most of the learning had been done not by pathologists, or even toxicologists, but rather by molecular biologists and neurochemists. That observation remains true today, even after all of the opiate receptors have been cloned, at a time when it is impossible to look at drug–receptor interactions in ways that were inconceivable only a decade ago.

In the preface to the first edition I also complained about the slow progress being made in more traditional, less “exotic” fields. The advent of the phenomenally popular *CSI* television show helped raise public awareness of crime scene investigation. Industry is certainly aware of the amazing progress and has not been slow to capitalize upon it, even to the extent of funding some badly needed research. The same kind of progress in understanding the effects of drug abuse has not occurred in the field of pathology, or any other medical specialties, for that matter. To the best of my knowledge, during the last decade, The National Institute of Drug Abuse (NIDA) has not funded even a single pathologist interested in studying the effects of abused drugs on the heart, or pancreas, or any other organ in the body; no pathologist sits on any of the NIH review boards. Some might say this is the very opposite of progress. There is very little difference between the way doctors treat cases of drug toxicity nowadays and the way they did so 30 years ago. The last really great advance in this field was the introduction of naloxone. “Compassionate,” or not, the medical management of sick drug users is no more a priority of our current administration than of the previous one.

Like it or not, the scientific study of drug abuse–related disease constitutes an important part of forensic science. When are drugs the cause of death and when do they cause impairment? It turns out that the metabolism of different drugs varies greatly from individual to individual. Some of these differences remain apparent even after death, but many, if not most, are not visible to the naked eye. Not many medical examiners have the training, let alone the equipment, to test for invisible disease.

Does a very high fluoxetine level in a dead child signify a lethal overdose, or attempted murder, or is it a fluke of nature? The questions are more than academic, because the answers may determine whether criminal charges will be filed against the parents. Accordingly, this second edition of the handbook contains new chapters on both toxicogenetics and on the genetics of sudden cardiac death. Anyone who felt that they had mastered the art of DNA had best rethink their conclusions. Far from being a developed discipline, DNA testing is still only in its infancy. Should there be a third edition of this book, it will no doubt focus largely on DNA-related science; a great deal more than matching up single nucleotide polymorphisms is involved.

Readers will also note the addition of a section on legal notions of causation. Doctors have known for years that the search for scientific truth is best carried on outside of the courtroom. What most doctors do not know is that in the minds of jury members, their opinions carry no more, and no less, weight than the opinion of any laboratory technician. Worse, both doctor and technician are likely to have only a vague idea of what constitutes proof, and what constitutes junk science.

But, in fact, there is an easy way to tell: just use the scientific method. Most of this book is concerned with forensic science, the clinical management of toxic patients, and the management of addicted patients. At some point there must be a convergence of these fields, and at some point all of these different disciplines become an evidence-based field. Case reports describing possible episodes of drug toxicity in solitary patients 30 years ago are insufficient to establish causation, not in the courtroom and not in the laboratory. Isolated post-mortem blood drug levels, no matter how “significant,” are insufficient to establish the cause of death. A great deal more work and

knowledge are required before that can be done. No matter how great the scientific advances of the next decade, there will be no real and lasting impact on everyday practice, at least not until what we do is, in fact, evidence based.

As should be apparent from the size of this volume, many individuals expended considerable energy to produce this book. It is probably a good thing that this book took so long to prepare because most of the truly exciting discoveries have occurred only in the last few years.

My thanks to all of the contributors, and my best wishes to the next editor. I do hope he or she will have more positive and exciting things to report.

Steven B. Karch, M.D., FFFLM

The Editor

Steven B. Karch, M.D., FFFLM, received his undergraduate degree from Brown University. He attended graduate school in anatomy and cell biology at Stanford University. He received his medical degree from Tulane University School of Medicine. Dr. Karch did postgraduate training in neuropathology at the Royal London Hospital and in cardiac pathology at Stanford University. For many years he was a consultant cardiac pathologist to San Francisco's Chief Medical Examiner.

In the U.K., Dr. Karch served as a consultant to the Crown and helped prepare the cases against serial murder Dr. Harold Shipman, who was subsequently convicted of murdering 248 of his patients. He has testified on drug abuse-related matters in courts around the world. He has a special interest in cases of alleged euthanasia, and in episodes where mothers are accused of murdering their children by the transference of drugs, either *in utero* or by breast feeding.

Dr. Karch is the author of nearly 100 papers and book chapters, most of which are concerned with the effects of drug abuse on the heart. He has published seven books. He is currently completing the fourth edition of *Pathology of Drug Abuse*, a widely used textbook. He is also working on a popular history of Napoleon and his doctors.

Dr. Karch is forensic science editor for Humana Press, and he serves on the editorial boards of the *Journal of Cardiovascular Toxicology*, the *Journal of Clinical Forensic Medicine* (London), *Forensic Science, Medicine and Pathology*, and *Clarke's Analysis of Drugs and Poisons*.

Dr. Karch was elected a fellow of the Faculty of Legal and Forensic Medicine, Royal College of Physicians (London) in 2006. He is also a fellow of the American Academy of Forensic Sciences, the Society of Forensic Toxicologists (SOFT), the National Association of Medical Examiners (NAME), the Royal Society of Medicine in London, and the Forensic Science Society of the U.K. He is a member of The International Association of Forensic Toxicologists (TIAFT).

INTRODUCTION

This chapter is concerned with the identification and analysis of physical evidence derived from drugs and drug users. The chapter begins with an introduction to the most popular synthetic routes preferred by clandestine drug makers. Sections are devoted to brief regulatory histories and overviews of the most common drugs (heroin, cocaine, and marijuana) as well as some of the lesser known licit and illicit drug agents. An overview is provided of what information is required to make a defensible forensic identification. This includes an introduction to drug logos, tablet markings and capsule imprints, and blotter acid. The remaining sections provide introductions to the various field and laboratory screening and confirmatory testing procedures. Techniques of comparative analysis are explained, and methods for comparing cocaine and heroin courtroom exhibits are presented. The trade names of commonly encountered chemicals are listed. The chapter concludes with tabular listings of controlled substances by schedule number.

1.1 DEFINITION AND SCHEDULING OF CONTROLLED SUBSTANCES

A “controlled substance” is a drug or substance of which the use, sale, or distribution is regulated by the federal government or a state government entity. These controlled substances are listed specifically or by classification on the federal level in the Controlled Substances Act (CSA) or in Part 1308 of the Code of Federal Regulations. The purpose of the CSA is to minimize the quantity of usable substances available to those who are likely to abuse them. At the same time, the CSA provides for the legitimate medical, scientific, and industrial needs of these substances in the U.S.

1.2 SCHEDULING OF CONTROLLED SUBSTANCES

Eight factors are considered when determining whether or not to schedule a drug as a controlled substance:

1. Actual or relative potential for abuse
2. Scientific evidence of pharmacological effect
3. State of current scientific knowledge
4. History of current pattern of abuse
5. Scope, duration, and significance of abuse
6. Risk to the public health
7. Psychic or physiological dependence liability
8. Immediate precursor

The definition of potential for abuse is based on individuals taking a drug of their own volition in sufficient amounts to cause a health hazard to themselves or to others in the community. Data are then collected to evaluate three factors: (1) actual abuse of the drug; (2) the clandestine manufacture of the drug; (3) trafficking and diversion of the drug or its precursors from legitimate channels into clandestine operations. Preclinical abuse liability studies are then conducted on animals to evaluate physiological responses to the drug. At this point, clinical abuse liability studies can be conducted with human subjects, which evaluate preference studies and epidemiology.

Accumulating scientific evidence of a drug's pharmacological effects involves examining the scientific data concerning whether the drug elicits a stimulant, depressant, narcotic, or hallucinogenic response. A determination can then be made regarding how closely the pharmacology of the drug resembles that of other drugs that are already controlled.

Evidence is also accumulated about the scientific data on the physical and chemical properties of the drug. This can include determining which salts and isomers are possible and which are available. There is also a concern for the ease of detection and identification using analytical chemistry. Because many controlled substances have the potential for clandestine synthesis, there is a requirement for evaluating precursors, possible synthetic routes, and theoretical yields in these syntheses. At this phase of the evaluation, medical uses are also evaluated.

The next three factors — (1) history and patterns of abuse; (2) scope, duration, and significance of abuse; and (3) risks to public health — all involve sociological and medical considerations. The results of these studies focus on data collection and population studies. Psychic and physiological dependence liability studies must be satisfied for a substance to be placed on Schedules II through V. This specific finding is not necessary to place a drug on Schedule I. A practical problem here is that it is not always easy to prove a development of dependence.

The last factor is one that can involve the forensic analyst. Under the law, an "immediate precursor" is defined as a substance that is an immediate chemical intermediary used or likely to be used in the manufacture of a specific controlled substance. Defining synthetic pathways in the clandestine production of illicit controlled substances requires knowledge possessed by the experienced analyst.

A controlled substance will be classified and named in one of five schedules. Schedule I includes drugs or other substances that have a high potential for abuse, no currently accepted use in the treatment of medical conditions, and little, if any, accepted safety criteria under the supervision of a medical professional. Use of these substances will almost always lead to abuse and dependence. Some of the more commonly encountered Schedule I controlled substances are heroin, marijuana, lysergic acid diethylamide (LSD), 3,4-methylenedioxym-amphetamine (MDA), and psilocybin mushrooms.

Progressing from Schedule II to Schedule V, abuse potential decreases. Schedule II controlled substances also include drugs or other substances that have a high potential for abuse, but also have some currently accepted, but severely restricted, medical uses. Abuse of Schedule II substances may lead to dependence, which can be both physical and psychological. Because Schedule II controlled substances do have some recognized medical uses, they are usually available to health professionals in the form of legitimate pharmaceutical preparations. Cocaine hydrochloride is still used as a topical anesthetic in some surgical procedures. Methamphetamine, up until a few years ago, was used in the form of Desoxyn to treat hyperactivity in children. Raw opium is included in Schedule II. Amobarbital and secobarbital, which are used as central nervous system depressants, are included, as is phencyclidine (PCP), which was used as a tranquilizer in veterinary pharmaceutical practices. In humans, PCP acts as a hallucinogen. Although many of the substances seized under Schedule II were not prepared by legitimate pharmaceutical entities, cocaine hydrochloride and methamphetamine are two examples of Schedule II drugs that, when confiscated as white to off-white powder or granules in plastic or glassine packets, have almost always been prepared on the illicit market for distribution. As one progresses from Schedules III through V, most legitimate pharmaceutical preparations are encountered.

1.3 CONTROLLED SUBSTANCE ANALOGUE ENFORCEMENT ACT OF 1986

In recent years, the phenomenon of controlled substance analogues and homologues has presented a most serious challenge to the control of drug trafficking and successful prosecution of clandestine laboratory operators. These homologues and analogues are synthesized drugs that are

chemically and pharmacologically similar to substances that are listed in the Controlled Substances Act, but which themselves are not specifically controlled by name. (The term “designer drug” is sometimes used to describe these substances.) The concept of synthesizing controlled substance analogues in an attempt to circumvent existing drug law was first noticed in the late 1960s. At about this time there were seizures of clandestine laboratories engaged in the production of analogues of controlled phenethylamines. In the 1970s variants of methaqualone and phencyclidine were being seized in clandestine laboratories. By the 1980s, Congress decided that the time had come to deal with this problem with a federal law enforcement initiative. The Controlled Substance Analogue Enforcement Act of 1986 amends the Comprehensive Drug Abuse Prevention and Control Act of 1970 by including the following section:

Section 203. A controlled substance analogue shall to the extent intended for human consumption, be treated, for the purposes of this title and title III as a controlled substance in schedule I.

The 99th Congress went on to define the meaning of the term “controlled substance analogue” as a substance:

- (i) the chemical structure of which is substantially similar to the chemical structure of a controlled substance in schedule I or II;
- (ii) which has a stimulant, depressant, or hallucinogenic effect on the central nervous system that is substantially similar to or greater than the stimulant, depressant, or hallucinogenic effect on the central nervous system of a controlled substance in schedule I or II; or
- (iii) with respect to a particular person, which person represents or intends to have a stimulant, depressant, or hallucinogenic effect on the central nervous system of a controlled substance in schedule I or II.

The Act goes on to exclude:

- (i) a controlled substance
- (ii) any substance for which there is an approved new drug application
- (iii) with respect to a particular person any substance, if an exemption is in effect for investigational use, for that person, under section 505 ... to the extent conduct with respect to such substance is pursuant to such exemption; or
- (iv) any substance to the extent not intended for human consumption before such an exemption takes effect with respect to that substance.

Treatment of exhibits falling under the purview of the federal court system is described in Public Law 91-513 or Part 1308 of the Code of Federal Regulations. Questions relating to controlled substance analogues and homologues can usually be answered by reference to the Controlled Substances Analogue and Enforcement Act of 1986.

1.4 CONTROLLED SUBSTANCES

1.4.1 Heroin

Whenever one thinks about drugs of abuse and addiction, heroin is one of the most recognized drugs. Heroin is a synthetic drug, produced from the morphine contained in the sap of the opium

poppy. The abuse of this particular controlled substance has been known for many years. The correct chemical nomenclature for heroin is O^3,O^6 -diacetylmorphine. Heroin is synthesized from morphine in a relatively simple process. The first synthesis of diacetylmorphine reported in the literature was in 1875 by two English chemists, G.H. Beckett and C.P. Alder Wright.¹ In 1898 in Elberfeld, Germany, the Farbenfabriken vorm. Friedrich Bayer & Co. produced the drug commercially. An employee of the company, H. Dresser, named the morphine product “heroin.”² There is no definitive documentation as to where the name “heroin” originated. However, it probably had its origin in the “heroic remedies” class of drugs of the day.

Heroin was used in place of codeine and morphine for patients suffering from lung diseases such as tuberculosis. Additionally, the Bayer Company advertised heroin as a cure for morphine addiction. The analgesic properties of the drug were very effective. However, the addictive properties were quite devastating. In 1924, Congress amended the Narcotic Drug Import and Export Act to prohibit the importation of opium for the manufacture of heroin. However, stockpiles were still available and could be legally prescribed by physicians. The 1925 International Opium Convention imposed drug controls that began to limit the supply of heroin from Europe. Shortly thereafter, the clandestine manufacture of heroin was reported in China. The supplies of opium in the Far East provided a ready source of morphine — the starting material for the synthesis. The medical use of heroin in the U.S. was not banned until July 19, 1956 with the passage of Public Law 728, which required all inventories to be surrendered to the federal government by November 19, 1956.

In the past 50 or so years, the source countries for opium used in clandestine heroin production have increased dramatically. Political and economic instability in many areas of the world accounts for much of the increased production of heroin. The opium that is used to produce the heroin that enters the U.S. today has four principal sources. Geographically all of these regions are characterized by a temperate climate with appropriate rainfall and proper soil conditions. However, there are differences in the quality of opium, the morphine content, and the number of harvests from each of these areas. Labor costs are minimal and the profit margins are extremely high for those in the upper echelons of heroin distribution networks.

1.4.1.1 Heroin Sources by Region

Southeast Asia — The “Golden Triangle” areas of Burma, China, and Laos are the three major source countries in this part of the world for the production of illicit opium. Of these three countries, 60 to 80% of the total world supply of heroin comes from Burma. Heroin destined for the U.S. transits a number of countries including Thailand, Hong Kong, Japan, Korea, the Philippines, Singapore, and Taiwan. Southeast Asian heroin is usually shipped to the U.S. in significant quantities by bulk cargo carriers. The techniques for hiding the heroin in the cargo are quite ingenious. The shipment of Southeast Asian (SEA) heroin in relatively small quantities is also commonplace. Criminal organizations in Nigeria have been deeply involved in the small-quantity smuggling of SEA heroin into the U.S. The “body carry” technique and ingestion are two of the better known methods of concealment by the Nigerians. SEA heroin is high quality and recognized by its white crystalline appearance. Although the cutting agents are numerous, caffeine and acetaminophen appear quite frequently.

Southwest Asia — Turkey, Iraq, Iran, Afghanistan, Pakistan, India, Lebanon, and the newly independent states of the former Soviet Union (NIS) are recognized as source countries in this part of the world. Trafficking of Southwest Asian heroin has been on the decline in the U.S. since the end of 1994. Southwest Asian heroin usage is more predominant in Europe than in the U.S. The Southwest Asian heroin that does arrive in the U.S. is normally transshipped through Europe, Africa, and the NIS. The political and economic conditions of the NIS and topography of the land make these countries ideal as transit countries for heroin smuggling. The rugged mountainous terrain and the absence of significant enforcement efforts enable traffickers to proceed unabated. Most Southwest Asian heroin trafficking groups in the originating countries, the transiting countries, and the U.S. are highly cohesive ethnic groups. These groups rely less on the bulk shipment and more on smaller

quantity commercial cargo smuggling techniques. Southwest Asian heroin is characterized by its off-white to tan powdery appearance as compared to the white SEA heroin. The purity of Southwest Asian heroin is only slightly lower than that of SEA heroin. The cutting agents are many: phenobarbital, caffeine, acetaminophen, and calcium carbonate appear quite frequently.

Central America — Mexico and Guatemala are the primary source countries for heroin in Central America. Mexico's long border with the U.S. provides easy access for smuggling and distribution networks. Smuggling is usually small scale and often involves illegal immigrants and migrant workers crossing into the U.S. Heroin distribution in the U.S. is primarily the work of Mexican immigrants from the States of Durango, Michoacan, Nuevo Leon, and Sinaloa. Concealment in motor vehicles, public transportation, external body carries, and commercial package express are common. This heroin usually ranges from a dark brown powder to a black tar. The most commonly encountered adulterants are amorphous (formless and indeterminate) materials and sugars. The dark color of Mexican heroin is attributed to processing by-products. The purity of Mexican heroin varies greatly from seizure to seizure.

South America — Heroin production in this part of the world is a relatively new phenomenon. Cultivation of opium has been documented along the Andean mountain range within Colombia in the areas of Cauca, Huila, Tolima, and Santaner. There have been a number of morphine base and heroin processing facilities seized in Colombia in the past few years. Smuggling of South American heroin into the U.S. increased dramatically in 1994 and 1995. The primary method of smuggling has been by Colombian couriers aboard commercial airliners using false-sided briefcases and luggage, hollowed out shoes, or by ingestion. Miami and New York are the primary ports of entry into the U.S. One advantage that the traffickers from South America have is the importation networks that are already in place for the distribution of cocaine into the U.S. Transshipment of this heroin through other South American countries and the Caribbean is also a common practice. South American heroin has many of the same physical characteristics of Southwest Asian heroin. However, the purity of South American heroin is higher, with fewer adulterants than Southwest Asian heroin. Cocaine in small quantities is oftentimes encountered in South American heroin exhibits. In such cases, it is not always clear whether the cocaine is present as a contaminant introduced due to common packaging locations of cocaine and heroin, or whether it has been added as an adulterant.

1.4.1.2 Isolation of Morphine and Heroin Production

There are some very specific methods for producing heroin. However, all involve the same four steps: (1) The opium poppy (*Papaver somniferum* L.) is cultivated; (2) the poppy head is scored and the opium latex is collected; (3) the morphine is isolated from the latex; and (4) the morphine is treated with an acetylating agent. Isolation of the morphine in Step 3 is accomplished using a rendition of one of the following five methods:

1. **Thiboumery and Mohr Process (TMP)** — This is the best known of the reported methods for isolating morphine followed by the acetylation to heroin. Dried opium latex is dissolved in three times its weight of hot water. The solution is filtered hot, which removes undissolved botanical substances. These undissolved botanicals are washed with hot water and filtered. This is done to ensure a maximized yield of morphine in the final product. The filtrate is reduced to half its volume by boiling off the water. The laboratory operator then adds to the filtrate a boiling solution of calcium hydroxide, which forms the water-soluble calcium morphinate. The precipitates, which include the insoluble alkaloids from the opium, and the insoluble materials from this step are filtered. These insolubles are then washed three more times with water and filtered. The resulting filtrate, which contains calcium morphinate still in solution, is then evaporated to a weight of approximately twice the weight of the original weight of the opium and then filtered. This results in a concentrated calcium morphinate solution, which is heated to a boil. Ammonium chloride is then added to reduce the pH below 9.85. When this solution cools, morphine base precipitates and is collected by filtration. The morphine base is dissolved in a minimum volume of warm hydrochloric acid. When this solution cools the morphine hydrochloride precipitates. The precipitated morphine hydrochloride is then isolated by filtration.

2. **Robertson and Gregory Process (RGP)** — This method is similar to TMP. The laboratory operator washes the opium with five to ten times its weight of cold water. The solution is then evaporated to a syrup, which is then re-extracted with cold water and filtered. The filtrate is evaporated until the specific gravity of the solution is 1.075. The solution is boiled and calcium chloride is added. Cold water is added to the calcium morphinate solution, which is then filtered. The solution is concentrated and the calcium morphinate then precipitates out of solution as the liquid evaporates. The calcium morphinate is then redissolved in water and filtered. To the filtrate is added ammonia, which allows the morphine base to precipitate. This morphine base can then be further treated to produce the pharmaceutical quality morphine.

The TMP and RGP are used by commercial suppliers for the initial isolation of morphine from opium. In clandestine laboratories, the same methodologies and rudimentary steps are followed. However, since the operators are using “bucket chemistry,” there are modifications to hasten and shortcut the processes.

Three other methods can then be utilized to convert the relatively crude morphine base through purification processes to high-quality morphine base or morphine hydrochloride crystals. Modifications of these purifications are used by clandestine laboratory operators.

3. **Barbier Purification** — The morphine base is dissolved in 80°C water. Tartaric acid is added until the solution becomes acidic to methyl orange. As the solution cools, morphine bitartrate precipitates, is filtered, washed with cold water, and dried. The morphine bitartrate is then dissolved in hot water and ammonia is added to pH 6. This results in a solution of morphine monotartrate. The laboratory operator then adds activated carbon black, sodium bisulfite, sodium acetate, and ammonium oxalate. This process results in a decolorization of the morphine. When this decolorization process is complete, ammonia is added to the solution, which results in white crystals of morphine base. These purified morphine base crystals are then filtered and dried. This high-quality morphine base is converted to morphine hydrochloride by adding 30% ethanolic HCl to a warm solution of morphine in ethanol. The morphine hydrochloride crystallizes from solution as the solution cools.
4. **Schwyzer Purification** — The acetone-insoluble morphine base (from either the TMB or RGP) is washed in with acetone. The morphine base is then re-crystallized from hot ethyl alcohol.
5. **Heumann Purification** — The laboratory operator washes the morphine base (from either the TMB or RGP) with trichloroethylene, followed by a cold 40% ethanol wash. This is subsequently followed by an aqueous acetone wash.

The quality of the clandestine product is usually evaluated by the color and texture of the morphine from one of these processes. If the clandestine laboratory is producing morphine as its end product, with the intention of selling the morphine for conversion by a second laboratory, the morphine will usually be very pure. However, if the operator continues with the acetylation of the morphine to heroin, the “intermediate” morphine will frequently be relatively impure.

Heroin can be produced synthetically, but requires a ten-step process and extensive expertise in synthetic organic chemistry. The total synthesis of morphine has been reported by Gates and Tschudi in 1952 and by Elad and Ginsburg in 1954.^{3,4} A more recent synthesis was reported by Rice in 1980.⁵ All these methods require considerable forensic expertise and result in low yield. There are also methods reported in the literature for converting codeine to morphine using an *O*-demethylation. The morphine can then be acetylated to heroin. One of these procedures is referred to as “homebake” and was described in the literature by Rapoport et al.⁶ This particular procedure has been reported only in New Zealand and Australia.

Acetylation of Morphine to Diacetylmorphine (Heroin) — This process involves placing dried morphine into a reaction vessel and adding excess acetic anhydride (Figure 1.4.1). Sometimes a co-solvent is also used. The mixture is heated to boiling and stirred for varying periods of time ranging from 30 min up to 3 or 4 h. The vessel and contents are cooled and diluted in cold water. A sodium carbonate solution is then added until precipitation of the heroin base is complete and

Figure 1.4.1 Clandestine laboratory synthesis of heroin.

settles to the bottom of the reaction vessel. The heroin base is then either filtered and dried or undergoes further processing to enhance the purity or to convert the base to heroin hydrochloride.

Processing By-Products and Degradation Products in Heroin — Pharmaceutical-grade heroin has a purity of greater than 99.5%. Impurities include morphine, the *O*-3- and *O*-6-monoacetylmorphines, and other alkaloidal impurities and processing by-products. The impurities found in clandestinely produced heroin include, but are certainly not limited to: the monoacetylmorphines, morphine, codeine, acetylcodeine, papaverine, noscapine, thebaine, meconine, thebaol, acetylthebaol, norlaudanisine, reticuline, and codamine. These impurities (from both quantitative and qualitative perspectives) are retained as the result of anomalies in processing methodologies.

1.4.2 Cocaine

The social implications of cocaine abuse in the U.S. has been the subject of extensive media coverage from the 1980s to the present day. As a result, the general public has acquired some of the terminology associated with the cocaine usage. “Smoking crack” and “snorting coke” are terms that have become well understood in the American culture from elementary school through adulthood. However, there are facts associated with this drug that are not well understood by the general public. There are documented historical aspects associated with coca and cocaine abuse that go back 500 years. Recognizing some of these historical aspects enables the public to place today’s problem in perspective. Cocaine addiction has been with society for well over 100 years.

There are four areas of interest this section will address: (1) Where does cocaine come from? (2) How is cocaine isolated from the coca plant? (3) What does one take into the body from cocaine purchased on the street? (4) How does the chemist analyzing the drug identify and distinguish between the different forms of cocaine?

Cocaine is a Schedule II controlled substance. The wording in Title 21, Part 1308.12(b)(4) of the Code of Federal Regulations states:

Coca leaves (9040) and any salt, compound, derivative or preparation of coca leaves (including cocaine (9041) and ecgonine (9180) and their salts, isomers, derivatives and salts of isomers and derivatives),

and any salt, compound, derivative, or preparation thereof which is chemically equivalent or identical with any of these substances, except that the substances shall not include decocanized coca leaves, or extractions of coca leaves, do not contain cocaine or ecgonine.

It is significant that the term “coca leaves” is the focal point of that part of the regulation controlling cocaine. The significance of this fact will become more apparent as this discussion progresses.

1.4.2.1 Sources of Cocaine

Cocaine is just one of the alkaloidal substances present in the coca leaf. Other molecules, some of them psychoactive (norcocaine being the most prominent), are shown in Figure 1.4.2. Cocaine is extracted from the leaves of the coca plant. The primary source of cocaine imported into the U.S. is South America, but the coca plant also grows in the Far East in Ceylon, Java, and India. The plant is cultivated in South America on the eastern slopes of the Andes in Peru and Bolivia. There are four varieties of coca plants — *Erythroxylon coca* var. *coca* (ECVC), *E. coca* var. *ipadu*, *E. novogranatense* var. *novogranatense*, and *E. novogranatense* var. *truxillense*.¹⁻³ ECVC is the variety that has been used for the manufacture of illicit cocaine. While cultivated in many countries of South America, Peru and Bolivia are the world's leading producers of the coca plant. Cocaine is present in the coca leaves from these countries at dry weight concentrations of from 0.1 to 1%. The average concentration of cocaine in the leaf is 0.7%. The coca shrub has a life expectancy of 50 years and can be harvested three or four times a year.

Figure 1.4.2 Substances present in coca leaf.

The method of isolating cocaine from the coca leaf does not require a high degree of technical expertise or experience. It requires no formal education or expensive scientific equipment or chemicals. In most instances the methodology is passed from one generation to the next.

1.4.2.2 Historical Considerations

Prior to the 1880s, the physiological properties of cocaine and the coca leaf were not readily distinguishable in the literature. During that year, H.H. Rusby and W.G. Mortimer made the distinction between the physiological properties of “isolated” cocaine and the coca leaf. Mortimer wrote:

[T]he properties of cocaine, remarkable as they are, lie in an altogether different direction from those of coca.¹

In 1884, two significant papers appeared in the literature. Sigmund Freud published the first of his five papers on the medicinal properties of cocaine.² A few months later, Karl Koller discovered the use of cocaine as local anesthetic.³ In 1886, Sir Arthur Conan Doyle, an eye specialist who had studied at Vienna General Hospital, where Freud and Koller made their discoveries, made reference to Sherlock Holmes’s use of cocaine in *The Sign of Four*.⁴ That same year in Atlanta, Georgia, John Pemberton introduced to this country, caught up in the frenzy of alcohol prohibition, a beverage consisting of coca leaf extracts, African kola nuts, and a sweet carbonated syrup. The product was named “Coca-Cola.”⁵ Pemberton received his inspiration from Angelo Mariani, a Corsican pharmacist working in Paris, who had been selling a coca leaf-Bordeaux wine tincture since the early 1860s. Mariani’s product was the most popular tonic of its time, and was used by celebrities, poets, popes, and presidents.⁶ Patterns of coca consumption changed dramatically in the 20th century. In the 19th century, cocaine was available only in the form of a botanical product or a botanical product in solution. When chemical houses, such as Merck, began to produce significant quantities of refined cocaine, episodes of toxicity became much more frequent, the views of the medical profession changed, and physicians lost much of their enthusiasm for the drug.

Until 1923, the primary source of cocaine was from the coca leaf. In that year, Richard Willstätter was able to synthesize a mixture of D-cocaine, L-cocaine, D-pseudococaine, and L-pseudococaine. This multistep synthesis requires a high degree of technical expertise in organic chemistry and results in low yields.⁷ These financial and technical factors make the extraction of cocaine from the coca leaf the method by which most, if not all, of the cocaine is isolated for distribution on both the licit and illicit markets.

1.4.2.3 Isolation and Purification

The extraction and isolation of cocaine from the coca leaf is not difficult. There is more than one way to do it. South American producers improvise depending on the availability of chemicals. All of the known production techniques involve three primary steps: (1) extraction of crude coca paste from the coca leaf; (2) purification of coca paste to cocaine base; and (3) conversion of cocaine base to cocaine hydrochloride. The paste and base laboratories in South America are deeply entrenched and widespread with thousands of operations, whereas the conversion laboratories are more sophisticated and centralized. They border on semi-industrial pilot-plant type laboratories involving a knowledge of chemistry and engineering.

The primary isolation method used until recently is a Solvent Extraction Technique. The essential methodology involves macerating a quantity of coca leaves with lime water, and then adding kerosene with stirring. After a while the kerosene is separated from the aqueous layer. A dilute sulfuric acid solution is added to the kerosene with stirring. This time the kerosene is separated

from the aqueous layer and set aside. It is common to save the kerosene for another extraction of the leaves. The aqueous layer is retained and neutralized with limestone or some other alkaline substance. The material that precipitates after the addition of limestone is crude coca paste containing anywhere from 30 to 80% cocaine, with the remainder of the cocaine matrix composed primarily of other alkaloids, hydrolysis products, and basic inorganic salts used in the processing. This solid material is isolated by filtration for purification of the cocaine.

The coca paste is then dissolved in dilute sulfuric acid, and dilute potassium permanganate solution is added to oxidize the impurities. This solution is then filtered, and ammonium hydroxide is added to the filtrate to precipitate cocaine base. This "cocaine" is not ready for shipment to the U.S. The cocaine will first be converted to hydrochloride for easier packaging, handling, and shipment.

A second method of isolating cocaine from the leaf, which is more predominant today, is the Acid Extraction Technique. In this method, the cocaine leaves are placed directly in the maceration pit with enough sulfuric acid to cover the leaves. The pit is a hole dug into the ground and lined with heavy-duty plastic. The leaves are macerated by workers who stomp in the sulfuric acid/coca leaf pit. This stomping leaches the cocaine base from the leaf and forms an aqueous solution of cocaine sulfate. This stomping can continue for a matter of hours to ensure maximum recovery of the cocaine.

After stomping is complete, the coca solution is poured through a coarse filter to remove the insolubles including the plant material. More sulfuric acid is added to the leaves and a second or even third extraction of the remaining cocaine will take place. Maximized recovery of cocaine is important to the laboratory operators. After the extractions and filterings are completed, an excess basic lime or carbonate solution is added to the acidic solution with stirring and neutralizing the excess acid and cocaine sulfate. A very crude coca paste forms. The addition of the base is monitored until the solution is basic to an ethanolic solution of phenolphthalein. The coca paste is then back-extracted with a small volume of kerosene. The solution sets until a separation of the layers occurs. The kerosene is then back-extracted this time with a dilute solution of sulfuric acid. Then, an inorganic base is added to precipitate the coca paste. This coca paste is essentially the same as that generated by the solvent extraction method. The advantage to this Acid Extraction Technique is that a minimal volume of organic solvent is required. And while it is more labor intensive, the cost of labor in Bolivia, the major producing country of coca paste, is very low when compared to the financial return.

The resultant cocaine base, produced by either technique, is dissolved in acetone, ether, or a mixture of both. A dilute solution of hydrochloric acid in acetone is then prepared. The two solutions are mixed and a precipitate of cocaine hydrochloride forms almost immediately and is allowed to settle to the bottom of the reaction vessel (usually an inexpensive bucket). The slurry will then be poured through clean bed sheets filtering the cocaine hydrochloride from the solvent. The sheets are then wrung dry to eliminate excess acetone, and the high-quality cocaine hydrochloride is dried in microwave ovens, under heat lamps, or in the sunlight. It is then a simple matter to package the cocaine hydrochloride for shipment. One of the more common packaging forms encountered in laboratories analyzing seizures of illicit cocaine is the "one kilo brick." This is a brick-shaped package of cocaine wrapped in tape or plastic, sometimes labeled with a logo, with the contents weighing near 1 kg. Once the cocaine hydrochloride arrives in the U.S., drug wholesalers may add mannitol or inositol as diluents, or procaine, benzocaine, lidocaine, or tetracaine as adulterants. This cocaine can then be sold on the underground market in the U.S. either in bulk or by repackaging into smaller containers.

1.4.2.4 Conversion to "Crack"

"Crack" is the term used on the street and even in some courtrooms to describe the form of cocaine base that has been converted from the cocaine hydrochloride and can be smoked in a pipe.

This procedure of conversion from the acid to the base is usually carried out in the U.S. Cocaine base usually appears in the form of a rock-like material, and is sometimes sold in plastic packets, glass vials, or other suitable packaging. Cocaine hydrochloride is normally ingested by inhalation through a tube or straw, or by injection. Cocaine base is ingested by smoking in an improvised glass pipe. Ingestion in this manner results in the cocaine entering the bloodstream through the lungs and rushes to the brain very quickly.

Cocaine hydrochloride is converted to cocaine base in one of two ways. The first method involves dissolving the cocaine hydrochloride in water and adding sodium bicarbonate or household ammonia. The water is then boiled for a short period until all of the precipitated cocaine base melts to an oil, and ice is added to the reaction vessel. This vessel will usually be a metal cooking pan or a deep glass bowl. As the water cools, chunks of cocaine base oil will solidify at the bottom of the cooking vessel. After all the cocaine base has formed, the water can be cooled and then poured off leaving the solid cocaine base, which is easily removed from the collection vessel. The cocaine base can be cut with a knife or broken into “rocks,” which can then be dried either under a heat lamp or in a microwave oven. It is not unusual when analyzing cocaine base produced from this method to identify sodium bicarbonate mixed with the rock-like material. This cocaine base sometimes has a high moisture content due to incomplete drying.

A second method of producing cocaine base from cocaine hydrochloride involves dissolving the salt (usually cocaine hydrochloride) in water. Sodium bicarbonate or household ammonia is added to the water and mixed well. Diethyl ether is then added to the solution and stirred. The mixture then separates into two layers with the ether layer on top of the aqueous layer. The ether is decanted leaving the water behind. The ether is then allowed to evaporate and high-quality cocaine base remains. If any of the adulterants mentioned previously (excluding sugars, which are diluents) are mixed with the cocaine hydrochloride prior to conversion, then they will also be converted to the base and will be a part of the rock-like material that results from this process. The term “free base” is used to describe this form of cocaine. Cocaine base in this form is also smoked in a glass pipe. However, residual (and sometimes substantial) amounts of ether remaining in these samples from the extraction process make ignition in a glass pipe very dangerous.

1.4.2.5 Other Coca Alkaloids

In the process of examining cocaine samples in the laboratory, it is not uncommon to identify other alkaloids and manufacturing by-products with the cocaine. These other alkaloids are carried over from the coca leaf in the extraction of the cocaine. Many manufacturing by-products result from the hydrolysis of the parent alkaloids (benzoylecgonine from cocaine, or truxillic acid from truxilline). As a forensic chemist, it is important to recognize the sources of these alkaloids as one progresses through an analytical scheme.

The major alkaloidal “impurities” present in the coca leaf that are carried over in the cocaine extraction are the *cis*- and *trans*-cinnamoylcocaines and the truxillines. There are 11 isomeric truxillic and truxinic acids resulting from the hydrolysis of truxilline. Another naturally occurring minor alkaloid from the coca leaf is tropacocaine. The concentration of tropacocaine will rarely, if ever, exceed 1% of the cocaine concentration and is well below the concentrations of the *cis*- and *trans*-cinnamoylcocaines and the truxillines. Two other alkaloids from the coca leaf which have been identified are cuscohygrine and hygrine. These two products are not found in cocaine, just in the leaf.

The second class of substances found in the analysis of cocaine samples is the result of degradation or hydrolysis. Ecgonine, benzoylecgonine, and methylecgonine found in cocaine samples will be the result of the hydrolysis of cocaine. It is important to recognize that some of these manufacturing by-products, such as ecgonine, can be detected by gas chromatography only if they are derivatized prior to injection. Methyl ecgonidine is a by-product of the hydrolysis of cocaine and is oftentimes identified in the laboratory by gas chromatography/mass spectrometry (GC/MS).

This artifact can also result from the thermal degradation of cocaine or the truxillines in the injection port of the GC. Benzoic acid is the other product identified when this decomposition occurs.

There are at least two substances that result directly from the permanganate oxidation of cocaine. *N*-Formyl cocaine results from oxidation of the *N*-methyl group of cocaine to an *N*-formyl group. Norcocaine is a hydrolysis product resulting from a Schiff's base intermediate during the permanganate oxidation. There is also evidence that norcocaine can result from the *N*-demethylation of cocaine, a consequence of the peroxides in diethyl ether.

1.4.2.6 Cocaine Adulterants

The primary adulterants identified in cocaine samples are procaine and benzocaine. Lidocaine is also found with less regularity. These adulterants are found in both the cocaine base and cocaine hydrochloride submissions. The primary diluents are mannitol and inositol. Many other sugars have been found, but not nearly to the same extent. Cocaine hydrochloride concentrations will usually range from 20 to 99%. The moisture content of cocaine hydrochloride is usually minimal. Cocaine base concentrations will usually range from 30 to 99%. There will usually be some moisture in cocaine base ("crack") submissions from the water/sodium bicarbonate or water/ammonia methods. The concentration of cocaine base ("free base") from the ether/sodium bicarbonate or ether/ammonia methods will usually be higher and free of water.

The methods for identifying cocaine in the laboratory include but are not limited to: infrared spectrophotometry (IR), nuclear magnetic resonance spectroscopy (NMR), mass spectrometry (MS), and gas chromatography (GC). IR and NMR will enable the analyst to distinguish between cocaine hydrochloride and cocaine base. However, it is not possible to identify the form in which the cocaine is present utilizing this instrumentation.

1.4.2.7 Conclusion

The user of either cocaine base or cocaine hydrochloride not only ingests the cocaine, but also other alkaloids from the coca plant, processing by-products, organic and inorganic reagents used in processing, diluents, and adulterants. There is no realistic way in which a cocaine user can ensure the quality of the cocaine purchases on the street, and "innocent" recreational drug use may provide more danger than the user would knowingly risk.

1.4.3 Marijuana

1.4.3.1 History and Terminology

Marijuana is a Schedule I controlled substance. In botanical terms, “marijuana” is defined as *Cannabis sativa* L. Legally, marijuana is defined as all parts of the plant *C. sativa* L. (and any of its varieties) whether growing or not, the seeds thereof, the resin extracted from any part of the plant, and every compound, manufacture, salt, derivative, mixture, or preparation of such plant; its seeds and resins. Such terms do not include the mature stalk of the plants, fibers produced from such plants, oils or cakes made from the pressed seeds of such plants, any other compound, manufacture, salt derivative, mixture or preparation of such mature stalks (except the resin extracted therefrom), fiber, oil or cake, pressed seed, or the sterilized seed which is incapable of germination.¹ Pharmaceutical preparations that contained the resinous extracts of cannabis were available on the commercial market from the 1900s to 1937. These products were prescribed for their analgesic and sedative effects. In 1937 the U.S. Food and Drug Administration declared these products to be of little medical utility, and they were removed from the market. Cannabis, in the forms of the plant material, hashish, and hashish oil, is the most abused illicit drug in the world.

Cannabis is cultivated in many areas of the world. Commercial *C. sativa* L. is referred to as “hemp.” The plant is cultivated for cloth and rope from its fiber. A valuable drying oil used in art and a substitute for linseed oil is available from the seeds. Bird seed mixtures are also found to contain sterilized marijuana seeds. In the early days of the U.S., hemp was grown in the New England colonies. Its cultivation spread south into Pennsylvania and Virginia. From there it spread south and west most notably into Kentucky and Missouri. Its abundance in the early days of the country is still evident by the fact that it still grows wild in many fields and along many roadways. The plant is now indigenous to many areas, and adapts easily to most soil and moderate climatic conditions.

Marijuana is classified as a hallucinogenic substance. The primary active constituents in the plant are cannabinal, cannabidiol, and the tetrahydrocannabinols, illustrated in Figure 1.4.3. The tetrahydrocannabinols (THCs) are the active components responsible for the hallucinogenic properties of marijuana. The THC of most interest is the Δ^9 tetrahydrocannabinol. The other THCs of interest in marijuana are the Δ^1 *cis*- and *trans*-tetrahydrocannabinols, the Δ^6 *cis*- and *trans*-tetrahydrocannabinols, and the Δ^3 and Δ^4 tetrahydrocannabinols. The concentrations vary dramatically from geographic area to geographic area, from field to field, and from sample to sample. This concentration range varies from less than 1% to as high as 30%. In recent hash oil exhibits, the highest official reported concentration of Δ^9 -THC is 43%.² Five other terms associated with marijuana are as follows:

Hashish: Resinous material removed from cannabis. Hashish is usually found in the form of a brown to black cake of resinous material. The material is ingested by smoking in pipes or by consuming in food.

Hashish oil: Extract of the marijuana plant which has been heated to remove the extracting solvents. The material exists as a colorless to brown or black oil or tar-like substance.

Sinsemilla: The flowering tops of the unfertilized female cannabis plant. (There are no seeds on such a plant.) Sinsemilla is usually considered a “gourmet” marijuana because of its appearance and relatively high concentrations of the THCs.

Thai sticks: Marijuana leaves tied around stems or narrow-diameter bamboo splints. Thai sticks are considered a high-quality product by the drug culture. The THC concentrations of the marijuana leaves on Thai sticks are higher than domestic marijuana. Unlike hashish and sinsemilla, seeds and small pieces of stalks and stems are found in Thai sticks.

Brick or Kilo: Marijuana compressed into a brick-shaped package with leaves, stems, stalk, and seeds. The pressed marijuana is usually tightly wrapped in paper and tape. This is the form of marijuana encountered in most large-scale seizures. These large-scale seizure packages weigh approximately

Figure 1.4.3 The primary active constituents in marijuana.

1000 g (1 kg). This is the packaging form of choice for clandestine operators because of the ease of handling, packaging, shipping, and distribution.

1.4.3.2 Laboratory Analysis

The specificity of a marijuana analysis is still a widely discussed topic among those in the forensic and legal communities. In the course of the past 25 years, the consensus of opinion concerning the analysis of marijuana has remained fairly consistent. In those situations where plant material is encountered, the marijuana is first examined using a stereomicroscope. The presence of the bear claw cystolithic hairs and other histological features are noted using a compound microscope. The plant material is then examined chemically using Duquenois–Levine reagent in a modified Duquenois–Levine testing sequence. These two tests are considered to be conclusive within the realm of existing scientific certainty in establishing the presence of marijuana.^{3–5}

The modified Duquenois–Levine test is conducted using Duquenois reagent, concentrated hydrochloric acid, and chloroform. The Duquenois reagent is prepared by dissolving 2 g of vanillin and 0.3 ml of acetaldehyde in 100 ml of ethanol. Small amounts (25 to 60 mg is usually sufficient) of suspected marijuana leaf is placed in a test tube and approximately 2 ml of Duquenois reagent is added. After 1 min, approximately 1 ml of concentrated hydrochloric acid is added. Small bubbles rise from the leaves in the liquid. These are carbon dioxide bubbles produced by the reaction of the hydrochloric acid with the calcium carbonate at the base of the cystolithic hair of the marijuana. A blue to blue-purple color forms very quickly in the solution. Approximately 1 ml of chloroform is then added to the Duquenois reagent/hydrochloric acid mixture. Because chloroform is not miscible with water, and because it is heavier than water, two liquid layers are visible in the tube — the Duquenois reagent/hydrochloric acid layer is on top, and the chloroform layer is on the bottom. After mixing with a vortex stirrer and on settling, the two layers are again clearly distin-

guishable. However, the chloroform layer has changed from clear to the blue to blue-purple color of the Duquenois reagent/hydrochloric acid mixture.

One variation in this testing process involves pouring off the Duquenois reagent sitting in the tube with the leaves before adding the hydrochloric acid. The remainder of the test is conducted using only the liquid. Another variation involves conducting the test in a porcelain spot plate. This works, although some analysts find the color change a bit more difficult to detect. A third variation involves extracting the cannabis resin with ether or some other solvent, separating the solvent from the leaves, allowing the solvent to evaporate, and conducting the modified Duquenois–Levine test on the extract.

Marquis reagent is prepared by mixing 1 ml of formaldehyde solution with 9 ml of sulfuric acid. The test is done by placing a small amount of sample (1 to 5 mg) into the depression of a spot plate, adding one or two drops of reagent, and observing the color produced. This color will usually be indicative of the class of compounds, and the first color is usually the most important. A weak response may fade, and samples containing sugar will char on standing because of the sulfuric acid. Marquis reagent produces the following results:

1. Purple with opiates (heroin, codeine).
2. Orange turning to brown with amphetamine and methamphetamine.
3. Black with a dark purple halo with 3,4-methylenedioxyamphetamine (MDA) and 3,4-methylenedioxymethamphetamine (MDMA).
4. Pink with aspirin.
5. Yellow with diphenhydramine.

A thin-layer chromatographic (TLC) analysis, which detects a systematic pattern of colored bands, can then be employed as an additional test.^{6,7} Though it is not required, some analysts will run a GC/MS analysis to identify the cannabinoids in the sample.

The solvent insoluble residue of hashish should be examined with the compound microscope. Cystolithic hairs, resin glands, and surface debris should be present. However, if most of the residue is composed of green leaf fragments, the material is pulverized marijuana or imitation hashish.

1.4.4 Peyote

Peyote is a cactus plant that grows in rocky soil in the wild. Historical records document use of the plant by Indians in northern Mexico from as far back as pre-Christian times, when it was used by the Chichimaec tribe in religious rites. The plant grows as small cylinder-like “buttons.” The buttons were used to relieve fatigue and hunger, and to treat victims of disease. The peyote buttons were used in group settings to achieve a trance state in tribal dances.⁸

It was used by native Americans in ritualistic ceremonies. In the U.S., peyote was cited in 1891 by James Mooney of the Bureau of American Ethnology.⁹ Mooney talked about the use of peyote by the Kiowa Indians, the Comanche Indians, and the Mescalero Apache Indians, all in the southern part of the country. In 1918, he came to the aid of the Indians by incorporating the “Native American Church” in Oklahoma to ensure their rights in the use of peyote in religious ceremonies. Although several bills have been introduced over the years, the U.S. Congress has never passed a law prohibiting the Indians’ religious use of peyote. Both mescaline and peyote are listed as Schedule I controlled substances in the Comprehensive Drug Abuse Prevention and Control Act of 1970.

The principal alkaloid of peyote responsible for its hallucinogenic response is mescaline, a derivative of β -phenethylamine. Chemically, mescaline is 3,4,5-trimethoxyphenethylamine. As illustrated in Figure 1.4.4, its structure is similar to the amphetamine group in general. Mescaline was first isolated from the peyote plant in 1894 by the German chemist A. Heffter.¹⁰ The first complete synthesis of mescaline was in 1919 by E. Späth.¹¹ The extent of abuse of illicit mescaline has not been accurately determined. The use of peyote buttons became popular in the 1950s and

Figure 1.4.4 Chemical structure of mescaline.

again in the period from 1967 to 1970. These two periods showed a dramatic increase in experimentation with hallucinogens in general.

1.4.5 Psilocybin Mushrooms

The naturally occurring indoles responsible for the hallucinogen properties in some species of mushrooms are psilocybin (Figure 1.4.5) and psilocin.¹² The use of hallucinogenic mushrooms dates to the 16th century, occurring during the coronation of Montezuma in 1502.⁸ In 1953, R.G. Wassen and V.P. Wasson were credited with the rediscovery of the ritual of the Indian cultures of Mexico and Central America.¹³ They were able to obtain samples of these mushrooms. The identification of the mushrooms as the species *Psilocybe* is credited to the French mycologist, Roger Heim.¹⁴

Albert Hofmann (the discoverer of lysergic acid diethylamine) and his colleagues at Sandoz Laboratories in Switzerland are credited with the isolation and identification of psilocybin (phosphorylated 4-hydroxydimethyltryptamine) and psilocin (4-hydroxydimethyltryptamine).¹⁵ Psilocybin was the major component in the mushrooms, and psilocin was found to be a minor component. However, psilocybin is very unstable and is readily metabolized to psilocin in the body. This phenomenon of phosphate cleavage from the psilocybin to form the psilocin occurs quite easily in the forensic science laboratory. This can be a concern in ensuring the specificity of identification.

The availability of the mushroom has existed worldwide wherever proper climactic conditions exist—that means plentiful rainfall. In the U.S., psilocybin mushrooms are reported to be plentiful in Florida, Hawaii,¹⁶ the Pacific Northwest, and Northern California.¹⁷ Mushrooms analyzed in the forensic science laboratory confirm the fact that the mushrooms spoil easily. The time factor between harvesting the mushrooms and the analysis proves to be the greatest detriment to successfully identifying the psilocybin or psilocin. Storage prior to shipment is best accomplished by drying the mushrooms. Entrepreneurs reportedly resort to storage of mushrooms in honey to preserve the psychedelic properties.¹⁸

Figure 1.4.5 Chemical structure of psilocin and psilocybin.

Progressing through the analytical scheme of separating and isolating the psilocybin and psilocin from the mushroom matrix, cleavage of the phosphate occurs quite easily. Prior to beginning the analysis, drying the mushrooms in a desiccator with phosphorus pentoxide ensures a dry starting material. In many instances, the clean-up procedure involves an extraction process carried out through a series of chloroform washes from a basic extract and resolution of the components by TLC. The spots or, more probably, streaks are then scraped from the plate, separated by a back-extraction, and then analyzed by IR. Direct analysis by GC is very difficult because both psilocybin and psilocin are highly polar and not suitable for direct GC analysis. Derivatization followed by GC/MS is an option except in those instances where the mushrooms have been preserved in sugar.¹⁹ With the development and availability of high-performance liquid chromatography (HPLC), the identification and quantitation of psilocybin and psilocyn in mushrooms are becoming more feasible for many forensic science laboratories.²⁰

Figure 1.4.6 Synthetic route utilized for the clandestine manufacture of LSD.

1.4.6 Lysergic Acid Diethylamide

LSD is a hallucinogenic substance produced from lysergic acid, a substance derived from the ergot fungus (*Clavica purpurea*), which grows on rye. It can also be derived from lysergic acid amide, which is found in morning glory seeds.¹ LSD is also referred to as LSD-25 because it was the 25th in a series of compounds produced by Dr. Albert Hofmann in Basel, Switzerland. Hoffman was interested in the chemistry of ergot compounds, especially their effect on circulation. He was trying to produce compounds that might improve circulation without exhibiting the other toxic effects associated with ergot poisoning. One of the products he produced was Methergine™, which is still in use today. When LSD-25 was first tested on animals, in 1938, the results were disappointing. Then, 5 years later, in 1943, Hoffman decided to reevaluate LSD-25. The hallucinogenic experience that ensued when he accidentally ingested some of the compound led to the start of experimentation with “psychedelic” drugs.

LSD is the most potent hallucinogenic substance known to humans. Dosages of LSD are measured in micrograms (one microgram equals one one-millionth of a gram). By comparison, dosage units of cocaine and heroin are measured in milligrams (one milligram equals one one-thousandth of a gram). LSD is available in the form of very small tablets (“microdots”), thin squares of gelatin (“window panes”), or impregnated on blotter paper (“blotter acid”). The most popular of these forms in the 1990s was blotter paper perforated into 1/4-in. squares. This paper is usually brightly colored with psychedelic designs or line drawings. There have been recent reports of LSD impregnated on sugar cubes.² Such LSD-laced sugar cubes were commonplace in the 1970s. The precursor to LSD, lysergic acid, is a Schedule III controlled substance. LSD is classified as a Schedule I controlled substance. The synthetic route utilized for the clandestine manufacture of LSD is shown in Figure 1.4.6.

1.4.7 Phencyclidine

The chemical nomenclature of phencyclidine (PCP) is phenylcyclohexylpiperidine. The term “PCP” is used most often when referring to this drug. The acronym PCP has two origins that

are consistent. In the 1960s phencyclidine was trafficked as a peace pill (“PeaCePill”). Phenylcyclohexylpiperidine can also account for the PCP acronym.

PCP was first synthesized in 1926.³ It was developed as a human anesthetic in 1957, and found use in veterinary medicine as a powerful tranquilizer. In 1965 human use was discontinued because, as the anesthetic wore off, confusional states and frightening hallucinations were common. Strangely, these side effects were viewed as desirable by those inclined to experiment with drugs. Today even the use of PCP as a primate anesthetic has been all but discontinued. In 1978, the commercial manufacture of PCP ceased and the drug was transferred from Schedule III to Schedule II of the Controlled Substances Act. Small amounts of PCP are manufactured for research purposes and as a drug standard.

The manufacture of PCP in clandestine laboratories is simple and inexpensive. Figure 1.4.7 shows three of the synthetic routes utilized for its illegal production. The first clandestinely produced PCP appeared in 1967 shortly after Parke Davis withdrew phencyclidine as a pharmaceutical.⁴ The clandestine laboratory production of PCP requires neither formal knowledge of chemistry nor a large inventory of laboratory equipment. The precursor chemicals produce phencyclidine when combined correctly using what is termed “bucket chemistry.” The opportunities for a contaminated product from a clandestine PCP are greatly enhanced because of the recognized simplicity of the chemical reactions in the production processes. The final product is often contaminated with starting materials, reaction intermediates, and by-products.⁵ Clandestine laboratory operators have been known to modify the manufacturing processes to obtain chemically related analogues capable of producing similar physiological responses. The most commonly encountered analogues are *N*-ethyl-1-phenylcyclohexylamine (PCE), 1-(1-phenylcyclohexyl)-pyrrolidine (PCPy), and 1-[1-(2-thienyl-cyclohexyl)]-piperidine (TCP).

In the 1960s, PCP was distributed as a white to off-white powder or crystalline material and ingested orally. In recent years, PCP has been encountered as the base and dissolved in diethyl ether. The liquid is then placed into small bottles that normally would hold commercial vanilla extract. This ether solution is then sprayed on leaves such as parsley and smoked. PCP is commonly encountered on long thin dark cigarettes (“Sherms”) that have been dipped in the PCP/ether solution.

1.4.8 Fentanyl

Fentanyl [the technical nomenclature is *N*-(1-phenethyl-4-piperidyl)propionanilide] is a synthetic narcotic analgesic approximately 50 to 100 times as potent as morphine.⁶ The drug had its origin in Belgium as a synthetic product of Janssen Pharmaceutica.⁷ In the 1960s in Europe and in the 1970s in the U.S., it was introduced for use as an anesthesia and for the relief of post-operative pain. Almost 70% of all surgical procedures in the U.S. use fentanyl for one of these purposes.⁸

Fentanyl has been called “synthetic heroin.” This is a misnomer. Victims of fentanyl overdoses were often heroin abusers with “tracks” and the typical paraphernalia. The fentanyls as a class of drugs are highly potent synthetic narcotic analgesics with all the properties of opiates and opiods.⁴ However, the fentanyl molecule does not resemble heroin. Fentanyl is strictly a synthetic product while the morphine used in heroin production is derived from the opium poppy.

Beginning in the late 1970s with -methyلفentanyl,⁹ nine homologues and one analogue (excluding enantiomers) of fentanyl appeared on the illicit marketplace.¹⁰ The degrees of potency vary among the fentanyl homologues and analogues. The potencies of the fentanyl derivatives are much higher than those of the parent compound. But the high potencies cited above explain why even dilute exhibits result in the deaths of users who believe they are dealing with heroin. Another name used by addicts when referring to fentanyl and its derivatives is “China White.” This term was first used to described substances seized and later identified as alpha-methyلفentanyl in 1981.¹¹

There are many fentanyl homologues and analogues. Because of the size and complexity of fentanyl derivatives, the interpretation of IR, MS, and NMR spectral data proves very valuable in elucidating specific structural information required for the identification of the material.¹⁰

Figure 1.4.7 Synthetic routes utilized for illegal production of PCP.

Continued.

Several synthetic routes are possible. As shown in Figure 1.4.8a and b, one of the methods requires that fentanyl precursor, *N*-(1-phenethyl)-4-piperidinyl) aniline, be produced first. Alternatively, fentanyl can be produced by reacting phenethylamine and methylacrylate to produce the phenethylamine diester (see Figure 1.4.9).

1.4.9 Phenethylamines

The class of compounds with the largest number of individual compounds on the illicit drug market is the phenethylamines. This class of compounds consists of a series of compounds having

Figure 1.4.7 Continued.

a phenethylamine skeleton. Phenethylamines are easily modified chemically by adding or changing substituents at various positions on the molecule. Phenethylamines fall into one of two categories in terms of physiological effects — these compounds are either stimulants or hallucinogens. Phenethylamines are suitable for clandestine laboratory production. The parent compound in the phenethylamine series is amphetamine, a central nervous system (CNS) stimulant. With this molecule, the modifications begin by adding a methyl group to the nitrogen on the side chain. The resulting structure is the most popular clandestinely produced controlled substance in the U.S. — methamphetamine (Figure 1.4.10).

Like amphetamine, methamphetamine is also a CNS stimulant. It is easily produced in clandestine laboratories using two basic synthetic routes. The traditional route used by “meth cooks” began with phenyl-2-propanone; however, when bulk sales were limited by law, most clandestine chemists began using ephedrine as a precursor (Figure 1.4.11), although, as illustrated in Figure 1.4.11, some now synthesize their own supply of phenyl-2-propanone, and still other routes are possible (Figure 1.4.12). New legislation has now limited bulk purchases of ephedrine in the U.S., though not in neighboring countries. And the chemical structure is such that further molecular synthetic modifications are easily accomplished, resulting in a number of homologues and analogues. Few of the synthetic modifications of phenethylamines by clandestine laboratory “chemists” are novel. Most have been documented either in the scientific literature or in underground scientific literature. And the Internet now provides answers to anyone tenacious enough to search for a simple method to synthesize any analogue or homologue of a phenethylamine.

The parent compound of a second set of phenethylamine homologues and analogues (Figure 1.4.13) is 3,4-methylenedioxyamphetamine (MDA). This compound was first reported in the literature in 1910.¹² In the mid-1980s, the *N*-methyl analogue of MDA came into vogue and was known then and is still referred to as “Ecstasy.” The synthesis of 3,4-methylenedioxymethamphetamine (MDMA) follows the same synthetic protocols as the less complicated phenethylamines. The clandestine laboratory operator or research chemist selectively adds one *N*-methyl group, an *N,N*-dimethyl group, an *N*-ethyl group, an *N*-propyl, an *N*-isopropyl group, and so on. In 1985 the *N*-hydroxy MDA derivative was reported.¹³ This was significant because here the modification involved the addition of a hydroxyl group as opposed to an alkyl substitution on the nitrogen. Clandestine laboratory synthesis of MDA and MDMA are shown in Figure 1.4.13 and Figure 1.4.14.

The identification of the phenethylamines in the laboratory requires great care because of the chemical and molecular similarities of the exhibits. IR combined with MS and NMR spectrometry

provide the most specificity in the identifications of phenethylamines in the forensic science laboratory.^{13,14} From a legal perspective, the laboratory identification of the phenethylamine is part 1 in the forensic process. If prosecution is an option and the phenethylamine in question is not specified as a controlled substance under Public Law 91-513¹⁵ or Part 1308 of the Code of Federal Regulations, another legal option is available.

In 1986, the U.S. Congress realized that the legal system was at a standstill in attempting to prosecute clandestine laboratory operators involved in molecular modification of phenethylamines and other homologues and analogues of controlled substances. The attempted closing of this loophole was the passage of the Controlled Substances Analogue and Enforcement Act of 1986.¹⁶

1.4.10 Methcathinone

Methcathinone (CAT) is a structural analogue of methamphetamine and cathinone (Figure 1.4.15 and Figure 1.4.16). It is potent and it, along with the parent compound, is easily manufactured. They are sold in the U.S. under the name CAT. Methcathinone is distributed as a white to off-white chunky powdered material and is sold in the hydrochloride salt form. Outside of the U.S., methcathinone is known as ephedrone and is a significant drug of abuse in Russia and some of the Baltic States.¹⁷

Methcathinone was permanently placed in Schedule I of the Controlled Substances Act in October 1993. Prior to its scheduling, two federal cases were effectively prosecuted in Ann Arbor and Marquette, Michigan, utilizing the analogue provision of the Controlled Substances Analogue and Enforcement Act of 1986.

Figure 1.4.15 Clandestine laboratory synthesis of methcathinone.

Figure 1.4.16 Clandestine laboratory synthesis of cathinone.

1.4.11 *Catha edulis* (Khat)

Khat consists of the young leaves and tender shoots of the *Catha edulis* plant that is chewed for its stimulant properties.¹⁸ *Catha edulis*, a species of the plant family Celastraceae, grows in eastern Africa and southern Arabia. Its effects are similar to the effects of amphetamine. The active ingredients in Khat are cathinone [(-)- α -aminopropiophenone], a Schedule I controlled substance that is quite unstable, and cathine [(+)-norpseudoephedrine], a Schedule IV controlled substance. Identification of cathinone in the laboratory presents problems because of time and storage requirements to minimize degradation.¹⁹ Some of the decomposition or transformation products of *C. edulis* are norpseudoephedrine, norephedrine, 3,6-dimethyl-2,5-diphenylpyrazine, and 1-phenyl-1,2-propanedione.²⁰

1.4.12 Anabolic Steroids

1.4.12.1 Regulatory History

In recent years anabolic steroid abuse has become a significant problem in the U.S. There are two physiological responses associated with anabolic steroids: **androgenic activity** induces the development of male secondary sex characteristics; **anabolic activity** promotes the growth of various tissues including muscle and blood cells. The male sex hormone testosterone is the prototype anabolic steroid. Individuals abuse these drugs in an attempt to improve athletic performance or body appearance. The more common agents are shown in Figure 1.4.17.

Black market availability of anabolic steroids has provided athletes and bodybuilders with a readily available supply of these drugs. Both human and veterinary steroid preparations are found in the steroid black market. Anabolic steroid preparations are formulated as tablets, capsules, and oil- and water-based injectable preparations. There is also a thriving black market for preparations that are either counterfeits of legitimate steroid preparations or are simply bogus.

Control of Steroids

In 1990, the U.S. Congress passed the Anabolic Steroid Control Act. This act placed anabolic steroids, along with their salts, esters, and isomers, as a class of drugs, into Schedule III of the Federal Controlled Substances Act (CSA). This law provided 27 names of steroids that were specifically defined under the CSA as anabolic steroids. This list, which is provided in the *Federal Code of Regulations*, is reproduced below.

- | | |
|------------------------------------|------------------------|
| 1. Boldenone | 15. Methenolone |
| 2. Chlorotestosterone | 16. Methyltestosterone |
| 3. Clostebol | 17. Mibolerone |
| 4. Dehydrochloromethyltestosterone | 18. Nandrolone |
| 5. Dihydrotestosterone | 19. Norethandrolone |
| 6. Drostanolone | 20. Oxandrolone |
| 7. Ethylestrenol | 21. Oxymesterone |
| 8. Fluoxymesterone | 22. Oxymetholone |
| 9. Formebolone | 23. Stanolone |
| 10. Mesterolone | 24. Stanozolol |
| 11. Methandienone | 25. Testolactone |
| 12. Methandranone | 26. Testosterone |
| 13. Methandriol | 27. Trenbolone |
| 14. Methandrostenolone | |

Unfortunately, the list contains three sets of duplicate names (chlorotestosterone and Clostebol; dihydrotestosterone and stanolone; and methandrostenolone and methandienone) as well as one name (methandranone) for a drug that did not exist. So, the actual number of different steroids specifically defined under the law as anabolic steroids is 23, not 27. Realizing that the list of 23

Figure 1.4.17 Common agents.

substances would not be all inclusive, Congress went on to define within the law the term “anabolic steroid” to mean “any drug or hormonal substance, chemically or pharmacologically related to testosterone (other than estrogens, progestins, and corticosteroids) and that promote muscle growth.”

The scheduling of anabolic steroids has necessitated forensic laboratories to analyze exhibits containing steroids. In those cases involving the detection of 1 or more of the 23 steroids specifically defined as anabolic steroids under the law, questions of legality are not likely to arise. However, when a steroid is identified that is not specifically defined under the law, it becomes necessary to further examine the substance to determine if it qualifies as an anabolic steroid under the definition of such a substance under the CSA. The forensic chemist must positively identify the steroid and convey to the pharmacologist the entire structure of the steroid. It then becomes the responsibility of the pharmacologist to determine the pharmacological activity, including effects on muscle growth, of the identified steroid.

Figure 1.4.18 Cyclopentanoperhydrophenanthrene.

1.4.12.2 Structure–Activity Relationship

The pharmacology of the identified steroid may be evaluated in at least two ways. The first, and most important way, is to examine the scientific, medical, and patent literature for data on the pharmacological effects of the steroid. Over the years, numerous steroids have been examined in animal and/or human studies for anabolic/androgenic activity. It is possible that the identified steroid will be among that group of steroids. The second method is to evaluate possible pharmacological activity using **structure–activity relationships**. Such analysis is based on the assumption of a relationship between the structure of the steroid and its pharmacological effects. Small alterations of chemical structure may enhance, diminish, eliminate, or have no effect on the pharmacological activity of the steroid. The structure–activity relationships of androgens and anabolic steroids have been reviewed extensively.^{1,2}

Extensive studies of the structure–activity relationships of anabolic/androgenic steroids have demonstrated that the following structural attributes are necessary for maximal androgenic and anabolic effects: rings A and B must be in the *trans* configuration;³ hydroxy function at C-17 must be in the β conformational state;^{5,6} and high electron density must be present in the area of C₂ and C₃.⁷ The presence of a keto or hydroxyl group at position 3 in the A-ring usually enhances androgenic and anabolic activity, but it is not absolutely necessary for these effects.⁷ A few examples of structural alterations that enhance anabolic activity include removal of the C-19 methyl group;⁸ methyl groups at the 2a and 7a positions;^{9,10} a fluorine at the 9a position; or a chlorine at the 4a position.^{10,11} To make it easier to visualize where these modifications are made in the ring structure, a numbered steroid skeletal ring structure, namely, the cyclopentanoperhydrophenanthrene ring, is shown in Figure 1.4.18.

It is essential to understand that structure–activity analysis can predict only whether or not a steroid is likely to produce androgenic/anabolic effects. It then becomes necessary to examine the steroid in the laboratory to determine whether the prediction is, in fact, true. It is also important to note that numerous studies performed over the years and designed to separate androgenic activity from anabolic activity have failed to obtain such a separation of pharmacological effect. That is, steroids found to possess androgenic activity also have anabolic activity, and vice versa. An examination of the scientific and medical literature reveals that there are, indeed, additional steroids that are not specifically listed in the law but that do, based on available data, probably produce androgenic/anabolic effects. A listing of some of these steroids is provided below.

Androisoaxazole	Mestanolone
Bolandiol	Methyltrienolone
Bolasterone	Norbolethone
Bolenol	Norclostebol
Flurazebol	Oxabolone Cypionate

Mebolazine	Quinbolone
Mesabolone	Stenbolone

1.4.12.3 Forensic Analysis

For the forensic chemist, when a steroid is tentatively identified, an additional problem arises, namely, obtaining an analytical standard. Many products found in the illicit U.S. market are commercially available only outside of the U.S. Locating and making contact with a foreign distributor is one problem. Requesting and then receiving a legitimate standard is another problem. The expense incurred in obtaining these standards can be quite high. Once the standard has been received, authentication then enters the analytical process. If a primary standard is unavailable, an optimized analytical process presents a real problem. Fortunately, most steroids received by forensic science laboratories are labeled directly or have labeled packaging. So a manufacturer can be identified, and there is a starting point for the chemist in confirming the material as a particular steroid.

There are no known color tests, crystal tests, or TLC methods that are specific to anabolic steroids. Screening can be accomplished by GLC or HPLC. GLC sometimes presents a problem because of thermal decomposition in the injection port, thereby resulting in several peaks. The steroid will not always be the largest peak. On-column injection will usually solve this problem. However, oil-base steroids rapidly foul or degrade GC columns. Samples in oils can be extracted with methanol/water 9:1 prior to injection onto a GC. Retention times for some anabolic steroids are quite long and nearly triple or quadruple that of heroin. Recognizing that several anabolic steroids are readily oxidized in polar, protic solvents vs. halogenated hydrocarbons, screening and analysis must be accomplished as soon as possible after isolation and dilution.

GC/MS does provide definitive spectra; however, different MS systems may provide differences in the spectra for the same steroid. These differences can be traced to the quality of the MS source and the injection liner, thermal decomposition products, and induced hydration reactions related to high source temperatures set by the MS. C^{13} NMR is the most rigorous identification technique. The limitation here is the need for pure samples and high sample concentrations. Identification by infrared alone can result in problems due to polymorphism. This can be minimized by ensuring that the sample and standard are recrystallized from the same solvent.

Ideally, all anabolic steroids should be identified using two analytical methodologies that yield the same conclusions. The collection of a library of analytical data on different anabolic steroids is essential for the subsequent identification of steroids sent to the laboratory. An ability to interpret MS data will be important in making an identification insofar as determining a molecular formula. Interpreting NMR data will be important in determining how substituents are attached to the parent steroid ring structure.

It should be noted that selected steroids, such as testosterone, nandrolone, methenolone, boldenone, methandriol, and trenbolone, will often be encountered by the laboratory, not as the parent drug, but instead as an ester. The type of ester will be dependent on the particular steroid. For example, nandrolone is primarily found as a decanoate, laurate, or phenpropionate ester. Testosterone, although it is found as a parent drug, is actually most commonly encountered as the propionate, enanthate, cypionate, decanoate, isocaproate, or undecanoate esters. Less commonly encountered testosterone esters include the acetate, valerate, and undecylenate esters. Methenolone is almost always found in either the acetate or enanthate esterified form.

Upon reaching the forensic science laboratory, steroid preparations will be handled differently depending on the way each preparation is formulated. Tablets can be handled by finely grinding and extracting with chloroform or methanol. Aqueous suspensions can be handled by dilution/solution with methanol for HPLC screening or by extraction with chloroform for GC screening. Oils require a more specialized extraction.

What steroids have been the most predominant in the U.S. in the past few years? Although the last decade has seen the introduction of many new “designer steroids,” the list of most abused steroids has changed very little in the past 10 years. From January 1990 to October 1994, the following steroids or their esters were identified by DEA laboratories. This list provides an objective evaluation of what this chemist has encountered in the not-too-distant past. The data on these particular steroids should form the basis of a reference collection for comparison with future submissions.

Steroids or Esters of a Steroid	Numbers of	
	Cases	Exhibits
Testosterone	260	882
Nandrolone	140	244
Methenolone	99	189
Methandrostenolone	76	158
Oxymetholone	67	103
Stanozolol	61	115
Fluoxymesterone	54	7
Methyltestosterone	48	75
Boldenone	24	28
Mesterolone	21	22
Oxandrolone	16	21
Trenbolone	13	20
Methandriol	10	8
Drostanolone	6	7
Mibolerone	4	7
Stanolone	2	2
Testolactone	1	1

Acknowledgment

The author wishes to acknowledge the assistance of Dr. James Tolliver, Pharmacologist, of the DEA Office of Diversion Control, for collaborating in the preparation of this work.

1.5 LEGITIMATE PHARMACEUTICAL PREPARATIONS

The Controlled Substances Act (CSA) of 1970 created a closed system for the production and distribution of legitimately manufactured controlled substances. The CSA includes contingencies to regulate the domestic commerce, importation, and exportation of these pharmaceutical preparations. Even with all of the controls that are in place, legitimate pharmaceuticals intended to help those in need are diverted onto the illegitimate market. Most of the diversion of these pharmaceuticals occurs at the retail rather than the wholesale level.

The analysis of pharmaceutical preparations in the forensic science laboratory is one of the most straightforward types of analysis. These samples are usually recognizable by their labels, which usually include the manufacturer's logo and name. There are some samples that even have the name of the product inscribed on the tablet or capsule. In those instances where the manufacturer's logo is not recognized, the *Physician's Desk Reference* (PDR) is a readily available source of information, which includes photographs and descriptions of the product along with information of the formulation. Another source of this information is the *Logo Index for Tablets and Capsules*.¹ This particular text lists data including inscriptions on most known products including generics. After the tablet or capsule has been tentatively identified in a reference text, it is the responsibility of the forensic chemist to conduct a series of analyses to verify the presence of a controlled substance. This verification process will usually consist of many of the same analytical processes utilized in the analysis and evaluation of any controlled substance.

1.5.1 Benzodiazepines

The benzodiazepines form one of the largest classes of abused pharmaceuticals. These products are sedative/hypnotics, tranquilizers, and anti-anxiety drugs; they produce a calming effect and are often prescribed as tranquilizers. The drugs in this class are numerous and are included under Schedule IV control because, while they do have a potential for abuse, there are recognized medical benefits that are both physiological and psychological. The most frequently diverted and abused benzodiazepines are alprazolam (Xanax) and diazepam (Valium). Other frequently abused benzodiazepines are lorazepam (Ativan), triazolam (Halcion), chlordiazepoxide (Librium), flurazepam (Dalmane), and temazepam (Restoril). Another phenomenon that has been noted for several years is the abuse of legitimate pharmaceuticals in conjunction with illicit controlled substances. Clonazepam (Klonopin) is just such a product. It is an anxiety reducer that is used in combination with methadone and heroin.

There has been a recent influx of flunitrazepam (Rohypnol) into the Gulf Coast and other areas of the U.S. This product is a benzodiazepine manufactured principally in Colombia, Mexico, and Switzerland. It is also manufactured in lesser amounts in Argentina, Brazil, Peru, Uruguay, and Venezuela. It is neither manufactured nor marketed legally in the U.S. This is a powerful drug reported to be seven to ten times more potent than diazepam.

1.5.2 Other Central Nervous System Depressants

The oldest of the synthetic sleep-inducing drugs dates back to 1862. Chloral hydrate is marketed as a soft gelatinous capsule under the name Noctec, and controlled under Schedule V. Its popularity declined after the introduction of barbiturates. Barbiturates are the drugs prescribed most frequently to induce sedation. Roughly 15 derivatives of barbituric acid are currently in use to calm nervous conditions. In larger doses they are used to induce sleep.

The actions of barbiturates fall into four categories. Some of the ultrashort acting barbiturates are hexobarbital (Sombulex), methohexital (Brevital), thiamylal (Surital), and thiopental (Pentothal). Short-acting and intermediate-acting barbiturates include pentobarbital (Nembutal), seco-

Figure 1.5.1 Clandestine laboratory synthesis of methaqualone.

barbital (Seconal), and amobarbital (Amytal). These three drugs have been among the most abused barbituric acid derivatives. Also included in these categories but not as abused are butabarbital (Butisol), talbutal (Lotusate), and aprobarbital (Alurate). The last category is the long-acting barbiturates. These drugs are used medicinally as sedatives, hypnotics, and anticonvulsants. The group includes phenobarbital (Luminal), mephobarbital or methylphenobarbital (Mebaral), and metharbital (Gemonil).

Three other CNS depressants that have been marketed as legitimate pharmaceutical preparations and have a history of abuse include glutethimide (Doriden), methaqualone (Quaalude, Parest, Mequin, Optimil, Somnafac, Sopor, and Mandrax), and meprobamate (Miltown, Equanil, and SK-Bamate). The route for the clandestine synthesis of methaqualone is shown in Figure 1.5.1.

1.5.3 Narcotic Analgesics

When one thinks of opium-like compounds, morphine and heroin immediately come to mind. However, there is another subset of this class of compounds that includes pharmaceutical preparations used to relieve pain, which are purchased legitimately or illegitimately from a pharmacy with a prescription. Frequently used pharmaceutical opiates include oxycodone (Percodan), hydro-morphone (Dilaudid), hydrocodone (Tussionex and Vicodin), pentazocine (Talwin), and codeine combinations such as Tylenol with Codeine and Empirin with Codeine. All of these compounds are addictive.

Along with Tylenol with Codeine and Empirin with Codeine, which are Schedule III controlled substances, codeine is also available in combination with another controlled substance (butalbital) and sold under the trade name of Fiorinal with Codeine. It is available with acetaminophen in Phenaphen. Codeine is available in liquid preparations under the manufacturers' names Cosanyl, Robitussin A-C, Cheracol, Cerase, and Pediacof. Because of the amounts of codeine in these preparations, they are controlled under Schedule V. There are also pharmaceutical codeine tablets, which contain no drug other than codeine and are controlled under Schedule II.

While the compounds listed above are considered opiates, there is another class of compounds also classified as narcotic, but with synthetic origins. Meperidine (Demerol) is one of the most widely used analgesics for the relief of pain. Methadone (Amidone and Dolophine) is another of these synthetic narcotics. It was synthesized during World War II by German scientists because of a morphine shortage. Although it is chemically unlike morphine or heroin, it produces many of the same effects and is often used to treat narcotic addictions.

Dextropropoxyphene is one of those drugs that falls into one of two controlled substance schedules. When marketed in dosage form under the trade names Darvon, Darvocet, Dolene, or Propacet, dextropropoxyphene is a Schedule IV controlled substance. However, when marketed in bulk non-dosage forms, dextropropoxyphene is a Schedule II controlled substance. The significance here is that the penalties for possession of a Schedule II controlled substance are usually much greater than for possession of a Schedule IV controlled substance.

1.5.4 Central Nervous System Stimulants

Amphetamine (Benzedrine and Biphphetamine), dextroamphetamine (Dexedrine), and methamphetamine (Desoxyn) are three of the best-known CNS stimulants and were prescribed for many years to treat narcolepsy. At one time, these drugs were sold over the counter without a prescription. For many years these drugs were sold as appetite suppressants. Their availability in the form of prescription drugs has all but been eliminated except under the close scrutiny of a physician. However, the clandestine laboratory production of methamphetamine in the form of a powder or granular material has been one of the major problems facing law enforcement personnel in the past 20 or so years in the U.S.

Phenmetrazine (Preludin) and methylphenidate (Ritalin) are two other CNS stimulants that have patterns of abuse similar to the amphetamine and methamphetamine products. In recent years, a number of pharmaceutical products have appeared on the market as appetite suppressants and as replacements for the amphetamines. These anorectic drugs include benzphetamine (Didrex), chlorphentermine (Pre-Sate), clortermine (Voramil), diethylpropion (Tenuate and Tepanil), fenfluramine (Pondimin), mazindol (Sanorex and Mazanor), phendimetrazine (Plegine, Bacarate, Melifat, Statobex, and Tanorex), and phentermine (Ionamin, Fastin, and Adipex-P).

1.5.5 Identifying Generic Products

There are a number of generic products on the market that are legitimate pharmaceutical preparations. These products will usually contain the active ingredient of the brand name product, but at the same time have a different formulation in the way of diluents and binders. These products are cataloged in various publications. When these products are encountered in the forensic science laboratory, the analyst will usually make a preliminary identification using one of the many publications listing the tablet or capsule's description and the code number that appears in the face of the product. This "preliminary" identification affords a starting point in the analytical process. The analyst will then proceed using the standard chemical techniques and instrumental methods to make an independent identification.

1.6 UNIQUE IDENTIFYING FACTORS

1.6.1 Packaging Logos

There are unique factors associated with controlled substance examinations that involve packaging. Heroin and cocaine are usually imported into the U.S. clandestinely packaged. Sometimes

this packaging takes the form of legitimate household or commercial products that have been hollowed out or have natural crevices into which drugs can be stored for shipment. These kinds of packages will usually be transported via commercial carriers to distributors who will reclaim the drugs and repackage them for street distribution. Sometimes drugs are shipped via human beings who store packages in body cavities, or swallow small packages in order to clear customs checks at points of entry. In these cases, it is not unusual for the packaging to break while in the body of the person transporting the drug. This usually results in severe injury or death.

Another common way of transporting controlled substances is to package the controlled substance in brick-size, 1-kg packages for shipment to the U.S. This is often the case with shipments of heroin, cocaine, and marijuana, and the packages are usually wrapped in paper or tape. Sometimes a logo, serving as a type of trademark for the illicit distributor, will be affixed. Logos can take the form of any number of designs. They are applied using a stamping or printing device. Some commonly encountered designs include, but are not limited to, animals, symbols from Greek mythology, replications of brand name product logos, replications of the names of political figures, cartoon characters, and numbers.

When a number of these logos are encountered, examinations can be conducted to determine whether two logos have a common source. If the examiner determines that two logos are the same, and were produced using the same printing or stamping device, then the two packages must have originated from the same source. This kind of information is especially useful in tracking distribution networks.

Glassine envelopes measuring approximately 1×2 in. are commonly used to distribute heroin "on the street" directly to the primary user. More often than not, these glassine envelopes have rubber-stamped images affixed. These rubber stamped images take many forms. Cartoon characters or words with social implications are common. The examiner can determine whether these rubber-stamped images have a commonality of source and use this information to track distribution patterns of heroin within a geographical area.

1.6.2 Tablet Markings and Capsule Imprints

Counterfeit tablets and capsules, which closely resemble tablets and capsules of legitimate pharmaceutical companies, are readily available on the clandestine market. They generally contain controlled substances that have been formulated in such a way as to mimic legitimate pharmaceutical preparations.¹ They are designed to be sold either on the clandestine or the legitimate market. These counterfeits sometimes are expertly prepared and closely resemble the pharmaceutical products that they are designed to represent. At other times, they are poorly made, inadequate representations of the products they are purported to represent.

The examiner in these types of cases will evaluate the suspected tablets or capsules by examining both the class and individual characteristics of the products. Legitimate products are usually prepared with few significant flaws on tablet or capsule surfaces. The lettering or numbering will be symmetrical in every way. The tablet surfaces will have minimal chips or gouges and will usually be symmetrical. The homogeneity of the tablet will be of the highest quality. Counterfeits will usually have tableting flaws. These flaws can take the forms of imperfect lettering or numbering, rough surfaces, or inconsistencies in the tablet formulation. This can result in different hardening characteristics of the tablet. Legitimate capsules will be highly symmetrical. The lettering or numbering will usually line up on both halves of the capsule.^{2,3}

In recent years, methamphetamine and amphetamine tablets and capsules, crafted to mimic Dexedrine and Benzedrine, have been encountered with some frequency. These two products were distributed and used quite extensively on the legitimate market up until the 1970s. And while they are still available commercially with a prescription, they have been controlled under Schedule II since 1972 and their legal distribution and usage in the medical community has become fairly limited. Counterfeit barbiturate, methaqualone, and benzodiazepine tablets, sometimes from doc-

umented clandestine source laboratories from 20 years ago, have been encountered in recent seizures. Counterfeit Quaalude, Mandrax, and Valium tablets are examples of legitimate trademark products that have been the favorites of clandestine laboratory operators. The “look-alike” market was especially lucrative in the 1970s and 1980s and became a \$50,000,000 a year industry.^{4,5}

A unique problem, encountered with regularity up until 1975, involved the refilling of capsules. Legitimate capsules were diverted from legitimate manufacturing sources. The capsules were then emptied of their contents and refilled with some innocuous material, such as starch or baking soda, and sold. The original filling, usually containing a controlled substance, was then diverted for sale on the illicit market. These capsules can usually be identified by imperfections in their surface characteristics. There may be small indentations on the gelatinous surface of the capsule and fingerprints indicating excessive handling. The seal holding both halves of the capsule together will not be tight. And there will usually be traces of powder around the seal of the capsule. Refilling capsules by hand or by improvised mechanical devices is not easy and usually results in these visible powder residues. A more common problem today is the refilling of over-the-counter capsules with heroin for distribution at the retail level.

A similar problem that is encountered with some frequency in the forensic science laboratory is the pre-packaged syringe from a hospital, which is labeled and supposed to contain an analgesic such as meperidine. Patients complain they are receiving no relief from the injection they have been given. The syringes are then sent to the laboratory for analysis. Not infrequently, they are found to contain water, substituted for the active drug by an addicted doctor or nurse.

1.6.3 Blotter Paper LSD

LSD has been available for years in the forms of small tablets (microdots), small gelatinous squares, clear plastic-like squares (window panes), powders or crystals, liquid, or in capsules. The most commonly encountered form of LSD available today is impregnated blotter paper. This LSD medium is prepared by dissolving the clandestinely produced LSD powder in an alcohol solution, and then spraying or soaking the paper with the solution. The alcohol solution used most frequently is EverClear, a commercial ethyl alcohol product available in liquor stores. This LSD-impregnated paper is referred to as “blotter acid.” It is usually distributed on sheets of paper perforated into $1/4 \times 1/4$ in. squares. These sheets of paper range in size to hold from 1 square up to 1000 squares. These sheets of blotter paper can be plain white or single colored with no design imprints. More often than not, there will be a brightly colored design on the paper. The design can be simple such as a black and white circle, or it can be extremely intricate. One such design was brightly colored and with a detailed depiction of the crucifixion of Jesus Christ. The design can cover each and every individual square of a 1000-perforated square sheet of paper, or one design can cover the entire sheet of blotter paper where each $1/4 \times 1/4$ in. perforation square makes up 1/1000 of the total design.

By examining the intricate designs on LSD blotter paper from different seizures, it is possible to determine whether there is a common source. Depending on the printing process and the quality of the image, the examiner may be able to characterize an exhibit as having originated from the image transfer process and a specific printing device. This ability to determine source commonality is most valuable in determining the origins of LSD exhibits seized from different parts of the world.

The processes described above are most valuable in linking seizures to a particular source. Investigators who are skillful and fortunate enough to seize printing or tabletting devices even without the actual controlled substances can have their efforts rewarded by terminating a controlled substance production operation. A qualified scientific examiner has the opportunity to use these devices as standards and to search reference collections of tablets, capsules, LSD blotter paper designs, or heroin or cocaine packaging logos to determine possible associations to past seizures. When this happens, the opportunity to eliminate another source of illicit drug distribution becomes a possibility.

1.7 ANALYZING DRUGS IN THE FORENSIC SCIENCE LABORATORY

1.7.1 Screening Tests

No other topic related to the identification of controlled substances causes as much controversy as testing specificity. Forensic science laboratories conduct two different categories of tests. Tests in the first category are called “screening tests.” They include a series of tests used to make a preliminary determination of whether a particular drug or class of drugs is present. It must be emphasized that screening tests are not used to positively identify any drug. At best, screening tests can only be used to determine the possibility that members of a particular class of drug may be present. Some say that screening tests can result in “false positives,” meaning either that the test indicates the possible presence of a controlled substance when none is present or that the test indicates the possible presence of one controlled substance when a different controlled substance is present. That should not be a problem, so long as it is understood that screening tests have very little if any specificity, and that a false positive test will only lead to more testing, not a false conclusion. The identification of any drug by a chemical analysis is a systematic process involving a progression from less specific methods to more specific methods. The most specific methods involve instrumental analyses. Properly trained scientists should know when a false positive is possible, and how to take steps to narrow the focus of the testing. The more tests used, the fewer the chances for error.

False negative screening tests also occur. Very weak or diluted samples containing controlled substances may yield a negative screening test. An example of this situation would be a 1% heroin sample cut with a brown powder. Testing this sample with Marquis reagent, which contains sulfuric acid and formaldehyde, may result in a charring of the brown powder and subsequent masking of the bleeding purple color characteristic of an opium alkaloid. Weak or old reagents may also yield false negatives. Examiner fallibility or inexperience in discerning colors may also result in false negatives. The possibility of a false negative leads many examiners to conduct a series of screening tests or, when warranted, to progress directly to more narrowly focused screening tests.

Specificity is the key to the forensic identification of controlled substances. There is no one method that will work as a specific test for any and all exhibits at any and all times. The choice of which specific method one utilizes must be determined by the type of controlled substance, the concentration of the controlled substance in the sample, the nature of the diluents and adulterants, the available instrumentation, and the experience of the examiner. There is an ongoing debate whether one can achieve this scientific certainty by combining a series of nonspecific tests. This is discussed later in this section.

1.7.1.1 Physical Characteristics

Occasionally an experienced forensic analyst can just look at an exhibit in a drug case and determine the probable nature of the substance. However, “probable natures” are not enough for

an identification, and most examiners will usually conduct more than one test before reporting the presence of a controlled substance. The morphology of botanical substances such as marijuana and the peyote cactus are familiar enough to many laboratory analysts. Marijuana is one of those controlled substances that is examined with such frequency in the laboratory that a preliminary identification is probable based on the morphology of the botanical substance, gross physical appearance, texture, and odor. However, even after a microscopic examination of the cystolithic hairs using a microscope, the modified Duquenois–Levine test is usually run to corroborate the identification. The peyote cactus with its button-like appearance is also unique. In a like manner, the identification of the opium poppy requires a confirmation of the morphine; and the identification of the psilocybin mushroom requires an identification of the psilocybin or the psilocin.

The physical characteristics of these four agronomic substances might enable an expert witness with a background in plant taxonomy and botany to make an identification based solely on these characteristics. The forensic analyst relies on the physical characteristics and corroborating chemical examinations to identify these materials as controlled substances.

1.7.1.2 Color Tests

The color test is usually the first chemical examination examiners conduct after a package suspected of containing controlled substances is opened and weighed. Small amounts of the unknown material are placed in depressions in a porcelain spot plate or a disposable plastic or glass spot plate. Chemical reagents are then added to the depressions and the results noted: color changes, the way in which the color changes take place (flashing or bleeding), the rate at which the color changes take place, and the intensity of the final colors. The most common color reagents are the Marquis reagent for opium alkaloids, amphetamines, and phenethylamines such as MDA or MDMA; cobalt thiocyanate reagent for cocaine and phencyclidine (PCP); Dille-Koppanyi reagent for barbiturates; Duquenois reagent for marijuana; and Ehrlich's reagent for LSD. A more complete listing of these tests is available in the literature.¹ Many of these tests are multistep and multicomponent.

These color tests are designed as a starting place for the examiner in deciding how to proceed as the pyramid of focus narrows in forming a conclusion. Adulterants and diluents can also cause color changes and are sometimes said to be responsible for "false positives." The resulting color changes are not really false. They simply reflect the presence of a substance that is not the primary focus of the analytical scheme. Problems of "false negatives" and "false positives" are usually recognized very early in the analytical scheme, and they are resolved logically and rationally.

1.7.1.3 Thin-Layer Chromatography

Thin-layer chromatography (TLC) is a separation technique. The method utilizes a glass plate that is usually coated evenly with a thin layer of adsorbant. The most commonly used adsorbant is silica gel. A small amount of the sample is put into solution with a chemical solvent. A capillary pipette is then used to place a small amount of the liquid onto the TLC plate approximately 2 cm from the bottom of the plate. A second capillary pipette containing a small amount of a known controlled substance in solution is used to place a second spot on the plate usually next to, but not overlapping, the first spot.

The plate is then placed into a tank containing a solvent system, which rises about 1 cm from the bottom of the tank. Through capillary action, the solvent will migrate up the plate, and the components of the unknown will usually separate as the solvent migrates. The separated components can usually be visualized using long-wave or shortwave ultraviolet light, a chemical spray, or some combination of both. The distance each sample migrates is then divided by the distance the solvent in the tank migrates up the plate (known as the R_f value). The result is then compared to published values that have been established for pure samples of the abused drugs. If one of the components of the unknown

migrates the same distance up the plate as the known, the examiner has another piece of corroborating information. If the unknown does not contain a component that migrates the same distance as the known, there are many explanations. Perhaps the known and unknown are not the same. Perhaps there is a component in the unknown solution that is binding the chemical of interest to the silica gel. The explanations for matches are numerous. The explanations for non-matches are just as numerous.

The literature is replete with values for drug/solvent migration ratios. However, these values can be affected by many factors, including the storage conditions of the TLC plates and solvent temperature. It is not uncommon for the R_f values in the laboratory to differ from those in the literature. The importance of a TLC analysis lies in its ability to separate components in a mixture. A match is another piece of corroborating information. A non-match can usually be explained.

Using TLC to identify marijuana, hashish, or hash oil is a much more complicated process than using it to identify other controlled substances.² The TLC analysis of cannabis exhibits results in a series of bands on the thin-layer plate. Depending on the solvent system, the number of bands can range from at least three to at least six bands.³ Each band will have a specific color and lie at a specified place on the plate corresponding to the known cannabinoids in a standard marijuana, hashish, or THC sample.⁴ The key point here is that this type of identification involves a specific chromatographic pattern as opposed to one spot where a known is compared directly with an unknown. Even with the increased specificity of a TLC analysis in the examination of cannabis or a cannabis derivative, a modified Duquenois–Levine test is suggested.

1.7.2 Confirmatory Chemical Tests

1.7.2.1 Microcrystal Identifications

Microcrystal tests are conducted using a polarized light microscope and chemical reagents. These microscopic examinations are not screening tests. The analyst will usually place a small amount of the sample on a microscope slide, add a chemical reagent, and note the formation of a specific crystal formation. These crystals are formed from specified reagents. There should be very little subjectivity in evaluating a microcrystal test.⁵ Either the crystal forms or it does not form. If the appropriate crystal forms in the presence of the reagent, the drug is present. If the crystal does not form and the drug is present, the problem is usually one in which the drug concentration is too dilute, or the reagent has outlived its shelf life.

One disadvantage of microcrystal tests is the absence of a hard copy of what the analyst sees. Unless a photograph is taken of the crystal formation, the examiner cannot present for review documentation of what he saw under the microscope. Microcrystal tests are an excellent way of evaluating the relative concentration of a drug in a sample to determine the kind of extraction technique for separation and further confirmation.

1.7.2.2 Gas Chromatography

Gas chromatography (GC) has been a standard operating procedure in forensic science laboratories for the past three decades. In this technique, a gaseous mobile phase is passed through a column containing a liquid-coated, stationary, solid, support phase. The most common form of GC uses a capillary column of a very fine diameter for separating the component of a mixture. The sample is usually put into solution using an organic solvent such as methanol. The liquid is then introduced into the injection port of the gas chromatograph using a fine needle syringe capable of delivering microliter quantities of the solution. The amount injected depends on the concentration of the sample: 1 μ l (one-one hundredth of a milliliter) of 1 mg of solute per 1 ml of solvent is a typical injection amount. The sample is vaporized in the heated injection port, and with the aid of a carrier gas travels through the long capillary column where the different components are separated. There are many different kinds of capillary columns with different internal coatings, lengths (which

can vary from one foot up to tens of meters), and diameters (measured in micrometers). This separation is determined by the polarity and molecular size of each component. Each component exits the column onto a detector. A flame ionization detector (FID) is the most common detector used in most laboratories. Other types of less frequently encountered detectors include the nitrogen phosphorus detector and the electron capture detector.

As each component elutes from the column through the FID, a signal is generated, which results in a “peak” on a recording device. The recorder is used to document the resulting data. This recorder is usually a part of a data station that not only generates a representation of the chromatogram on a monitor, but also controls instrument parameters and ensures the consistency of the analysis. The peaks of interest are evaluated by their retention times (RTs) and by the areas under the peaks. The retention time data can be used either as confirmation of the probable identity of the substance generating the peak, or the data can be evaluated as screening information to determine the possible presence of a controlled substance. These RT data are compared to the retention time of a known standard injected onto the same column in the same instrument at the same temperature and rate flow conditions. The RTs of the known and the unknown should be almost the same within a very narrow window. The area under the peak can be used to quantitatively determine the relative concentration of the substance.

There are some disadvantages of GC. Retention times are not absolute and usually fall within a narrow window. Other compounds may fall within this same RT window. One way to overcome this problem is to analyze the same sample using a second capillary column with a different internal coating and to note its retention time as compared to the known standard. The values should be the same within a narrow RT window. A second disadvantage of GC is that some samples degrade in the injection liner at high temperatures and must be evaluated by using a derivatizing agent. This derivatizing agent is added to the drug and forms a molecular complex. The molecule complex remains intact as it passes from the injection port, through the column, and onto the detector.

GC by itself is a very powerful tool for the forensic analyst. Its most useful application today remains one in which it is interfaced with a mass spectrometer (mass selective detector), which serves as a detector and separate instrumental identification method unto itself. Gas chromatography/mass spectrometry (GS/MS) is discussed later in this section.

1.7.2.3 High-Performance Liquid Chromatography

This chromatographic technique is also a separation technique, but with a bit more selectivity than GC. In high-performance liquid chromatography (HPLC), the mobile phase is a liquid and the stationary phase is a solid support or a liquid-coated solid support. In GC, a carrier gas is used to carry the sample through the chromatography column. In HPLC, a high-pressure pump is used to carry the solvent containing the compound of interest through the column. Separation results from selective interactions between the stationary phase and the liquid mobile phase.⁶ Unlike GC, the mobile phase plays a major role in the separation. HPLC can be used for the direct analysis of a wide spectrum of compounds and is not dependent on solute volatility or polarity. The operator need not worry about chemical changes in the molecule that can occur in GC due to thermal degradation.

HPLC chromatograms are evaluated based on retention time and area under the peak of interest. Retention time is not an absolute value, but a time within a narrowly defined window. The five basic parts of the liquid chromatograph include the solvent reservoir, the pump, the sample injection system, the column, and the detector. A recorder is used to document the resulting data. This recorder is usually a part of a data station that controls instrument parameters and ensures the consistency of the analysis. The most common detectors are the ultraviolet/visible detector (UV/VIS), the fluorescence detector, the electrochemical detector, the refractive index detector, and the mass spectrometer. The UV/VIS detector is the most widely used device, and it is dependent on the ability of the solute to absorb UV or visible light. The variable wavelength detector allows

the analyst to select any wavelength in the UV or visible range. The diode array or rapid scan detector is also used, which allows a rapid scan of the entire UV spectrum to identify the components eluting from the column.

Because the components elute from the UV detector in solution, they do not undergo degradation or destruction. This one very useful characteristic of HPLC affords the analyst the option of collecting fractions of the eluent for further analysis. This is not possible in GC because the eluent is destroyed by the FID.

1.7.2.4 Capillary Electrophoresis

Capillary electrophoresis (CE) is a technique that separates components on the basis of charge-to-mass ratios under the influence of an electrical field. It uses high voltage for fast separations and high efficiencies. Osmotic flow is the main driving force in CE, especially at higher pH values, and results primarily from the interaction of positive ions in solution with the silanol groups on the capillary in the presence of an applied field. Narrow bore capillary columns of uncoated fused silica are used for heat dissipation during the separation process. The detector is normally a UV detector.

Micellar electrokinetic capillary chromatography (MECC) is a form of CE that allows for the separation of cations, neutral solutes, and anions.

CE has several advantages over HPLC and GC. The method can be used with ionic and neutral solutes, which present problems in GC. There is a higher efficiency, resolving power, and speed of analysis compared to HPLC. From a cost perspective, CE requires much less solvent than HPLC, and the CE capillary column is much less expensive than the HPLC or GC capillary columns. Two disadvantages of CE are the limited sensitivity for UV detection (30 to 100 times less than that of HPLC); and fraction collection is troublesome because of mechanical problems and small sample size. This technique uses a micelle as a run buffer additive to give separations that are both electrophoretic and chromatographic.

One of the advantages of MECC is the ability to separate racemic mixtures of compounds into the D- and L-isomers. This is an ability that is extremely valuable when identifying compounds where one isomer is controlled (dextropropoxyphene) and the other isomer is not controlled (levopropoxyphene). This is usually accomplished by adding cyclodextrins to the run buffer.

1.7.2.5 Infrared Spectrophotometry

Infrared (IR) spectrophotometry is one of the most specific instrumental methods for the identification of a controlled substance. A pure drug as a thin film on a KBr salt plate, or as crystals mounted in a KBr matrix, is placed into the sample compartment of the IR spectrophotometer. A source of electromagnetic radiation in the form of light from a Nernst glower passes light through the sample. The instrument, through a mechanical means, splits the beam into a reference beam and an incident beam. The reference beam passes unobstructed through a monochromator to a photometer; the incident beam passes through the mounted sample through the same monochromator to the photometer. The reference beam passes 100% unobstructed to the photometer. The incident beam passing through the sample has some of its energy absorbed by the sample. This energy is absorbed at different wavelengths across the infrared spectrum from 4000 cm^{-1} down to 250 cm^{-1} . The amount of relative absorption and where on this spectrum the absorption takes place are dependent on the molecular structure and, more specifically, the functional groups of the drug. Different functional groups and molecular interactions brought on by symmetrical and asymmetrical molecular stretching vibrations and in-plane and out-of-plane bending vibrations result in a number of peaks and valleys on the IR chart. The resultant spectrum is usually formed on an x/y coordinate axis. The wavelength (μ) or wave number (cm^{-1}) where the absorption occurs is depicted on the

x -axis, and a measure of the amount of light absorbed by the sample, but usually referenced by transmittance units from 0 to 100%, is depicted on the y -axis.

The IR spectrum of a suspected drug results in a specific pattern that can be used to positively determine the identity of the substance. For most controlled substances, the resulting spectrum consists of 20 to 70 peaks. These peaks form a pattern that is unique to the chemical structure of the drug. This pattern can then be compared with a reference IR spectrum of a primary drug standard. If the analyst determines that the two spectra match within the limits of scientific certainty, an identification is possible. It is rarely, if ever, possible to overlay the reference spectra with the spectra of the unknown and have a “perfect match.” The analyst is looking for a match in the patterns. Any shifts in peak intensity or wave number must be evaluated in conjunction with the pattern. Small shifts of 1 or 2 cm^{-1} and minor intensity variations of individual peaks are expected. However, major variations must be evaluated on a case by case basis. Some authors refer to IR as a “fingerprint” identification method. This implies an ability to overlay two spectra and obtain a perfect match in every way. This degree of perfection is rarely, if ever, possible.

Another factor that must be considered is that when two spectra are being compared peak-by-peak as opposed to pattern-by-pattern, they ideally should be from the same instrument and collected at about the same time. Comparing a literature reference spectrum with an unknown for a pattern match is acceptable. Comparing the same literature reference spectrum wave number by wave number, absolute transmittance value by absolute transmittance value will probably result in minor differences.

IR does have limitations. To obtain an acceptable spectrum, the sample must be very clean and dry. For forensic exhibits, this usually means that most samples must go through extraction processes to remove impurities. In the past, sample size was a problem. However, because of advances in Fourier transform IR technology and the interfacing of an IR spectrophotometer with a microscope, evaluating microgram quantities of a sample results in excellent spectra that are conclusive for the identification of a controlled substance. IR has very definite limitations in its ability to quantitate controlled substances, and differentiating some isomers of controlled substances can pose problems.

1.7.2.6 Gas Chromatography/Mass Spectrometry

GC/MS is by far the most popular method of identifying controlled substances in the forensic science laboratory. In this method, a gas chromatograph is interfaced with a mass selective detector (MSD). The sample undergoing an examination is placed into solution with a solvent such as methanol. A very small injection volume of 1 or 2 μl is injected into the GC injection port. It then travels through the column where the different components of the sample are separated. The separated components can then be directed into the ionization chamber of MSD where they are bombarded by an electron beam. In electron impact gas chromatography/mass spectrometry (EI MS), high-energy electrons impact the separated component molecules. The resulting spectrum of each component is typically complex with a large number of mass fragments. These fragments are represented as peaks of varying intensity that provide the basis for comparison with a primary reference standard. The components are then ionized and positively charged. This ionization also results in a fission or fragmentation process. The molecular fragments traverse into a magnetic field where they are separated according to their masses. In this magnetic field, larger mass fragments are less affected by the magnetic field, and smaller fragments are more affected and undergo a deflection. Upon exiting the magnetic field, these fragments impact a detector losing the charge generated by the beam of electrons impacting the sample. The result of this fragmentation process is a pattern unique for the substance that is being analyzed.

The resulting mass spectrum consists of an x/y coordinate axis. The numerical value on the x -axis represents the mass number determined by the number of neutrons and protons in the nucleus. It is usually the molecular weight of a specific fragment. The largest magnitude peak on the x -axis

will often be the **molecular ion** and will represent the molecular weight of the unfragmented compound. There will usually be a very small peak to the right of the molecular ion which represents the molecular weight plus 1. The y-axis represents the relative abundance of each peak comprising the mass spectrum. The tallest peak on the y-axis is the **base peak** and represents that part of the molecule that is the most stable and undergoes the least amount of fragmentation. The base peak is assigned a relative abundance value of 100. The other peaks in the resulting spectrum are assigned relative values along the y-axis.

The numerical values on the x- and y-axis are calculated and assigned by the data station, which is interfaced with the mass spectrometer. The accuracy of these numbers is predicated on the fact that the instrument has been properly tuned. This tuning process can be compared to checking the channel tuning on a television set. This might be accomplished by opening a television guide to determine what programs are scheduled at a particular hour. The television is then turned on and the program for each channel checked. If the programs cited in the television magazine appear on corresponding channels at the proper times, the television has been proved to be properly tuned. The tuning of a mass analyzer presents an analogous situation.

The tuning process of a mass analyzer involves a procedure in which a chemical of a known molecular weight and fragmentation pattern is analyzed and the resulting data evaluated. This process includes verifying instrument parameters and the resulting spectrum. If the response of the tuning process falls within specified limits, the mass spectrometer is deemed operationally reliable, and the resulting data can be considered reliable. One such chemical used to tune mass spectrometers is perfluorotributylamine (PFTBA).

Fragmentation patterns of controlled substances are typically unique. Once a fragmentation pattern has been obtained, the forensic analyst should be able to explain the major peaks of the spectrum and relate them to the molecular structure. If properly evaluated, mass spectral data can usually be used to form a conclusion as to the identity of a controlled substance.

GC/MS has many advantages in the analysis of controlled substances. The sample being analyzed need not be pure. Multicomponent samples are separated and each soluble organic component can be individually identified. The analyst must be aware of isomeric compounds that have very similar chemical structures and similar fragmentation patterns. These kinds of situations can usually be handled by noting the GC retention time data to discriminate between similar compounds. Possible coelution of compounds from the capillary GC column and thermal degradation as noted in the gas chromatography section of this chapter should also be recognized. GC/MS does not allow the forensic analyst to directly identify the salt form of the drug. This task can be accomplished by considering the solubility properties of the drug being analyzed. In using this knowledge and performing extractions prior to injection onto the GC column, the salt form can be determined indirectly.

When all methods of instrumental analysis of controlled substances are considered, GC/MS is recognized in most instances as one of the efficient analytical techniques. If the analyst is cognizant of maintaining instrument reliability standards and the guidelines of mass spectral interpretation, GC/MS affords one of the highest degrees of specificity in the identification of controlled substances.

1.7.2.7 Nuclear Magnetic Resonance Spectroscopy

Nuclear magnetic resonance (NMR) spectroscopy is one of the most powerful instrumental techniques available to the forensic chemist. In those laboratories fortunate enough to have NMR technology, extensive capabilities exist. Data interpretation of NMR spectra requires a high degree of expertise. This instrumental technique allows the analyst to detect paramagnetic atoms. (^1H , ^2H , ^{13}C , ^{15}N , ^{17}O , ^{31}P , ^{11}B , and ^{19}F are examples.) Most forensic applications of NMR focus on ^1H and ^{13}C . The resonant frequency of hydrogen (^1H) in the current high-field magnets ranges from 200 to 750 MHz. This instrument generates a high magnetic field more than capable of damaging encrypted data on the back of a credit card. The NMR is a very expensive instrument requiring a high degree of specialized expertise to maintain and interpret the resulting data. The NMR is the one instrument that affords the

analyst the ability to determine both the molecular structure and the three-dimensional orientation of some individual atoms of the molecule. This means that structural isomers can be determined directly. However, the extent of this kind of information is usually required only by research scientists in those instances where no other information is available from other instrumental methods, or where no primary analytical standard is available to confirm the presence of a controlled substance.

The major component of the NMR spectrometer is a high-field super-conducting magnet. The sample is dissolved in a deuterated solvent and then transferred to a long cylindrical glass tube usually measuring 5 mm in diameter. The tube is placed into the NMR probe located near the center of the magnetic field. In proton NMR, the magnetic field causes the hydrogen atoms on the molecule to orient in a particular direction. To obtain high-resolution spectra, the field produced by the magnet must be homogeneous over the entire area of the sample in the probe. The resonance frequencies for all protons in a molecule may be different. These frequencies are dependent on the molecular environment of the nucleus. This correlation between resonance frequencies and molecular environment enables the analyst to make judgments regarding the structure of the drug being analyzed.

The NMR spectrum is traced on a two-dimensional *x/y* coordinate axis. By evaluating an NMR proton spectrum, an analyst can determine an important factor that facilitates the identification of the compound — the area under each peak indicates the number of nuclei that are undergoing a transition and the number of protons that are present.

There are other types of examinations that are possible with high-field NMR. A carbon-13 (^{13}C) evaluation enables an analyst to determine the number of carbons and their relative positioning in the molecule. ^{13}C is an isotope of the more abundant ^{12}C . About 1% of naturally occurring carbon is ^{13}C . There are two additional NMR “2D experiments” that are very valuable to the forensic analyst. Correlation spectroscopy (COSY) measures proton to proton (^1H to ^1H) interactions; and nuclear overhauser effect spectroscopy (NOESY) measures the interaction of protons that are close to one another, but not necessarily on adjoining atoms. Carbon-13, COSY, and NOESY spectra are all much more difficult to interpret and require specialized knowledge.

In the forensic analysis of controlled substances, most molecules comprise carbon and hydrogen. Proton NMR provides a unique spectral pattern that can be used to identify a controlled substance. This pattern also enables the analyst to distinguish between the basic and a salt form of the drug. NMR cannot distinguish halogenated salt forms. For instance, it cannot distinguish between heroin hydrochloride and heroin hydrobromide. But it can distinguish between a heroin salt and heroin base.

1.7.3 Controlled Substances Examinations

Every examination made by a forensic chemist has a potential legal ramification or consequence. Forensic chemists must be prepared to depart from the familiar natural science setting of the

laboratory and to enter the confrontational setting of the courtroom and be able to communicate with a prosecuting attorney, a defense attorney, a judge, 12 jurors, and on occasion, the press. The forensic chemist must be able to explain the significance of complicated analytical procedures to individuals with little or no scientific training. If the forensic analyst is to have any credibility on the witness stand, he must be able to describe what he has done in terminology understood by those individuals with whom he is communicating.

1.7.3.1 Identifying and Quantitating Controlled Substances

Whenever a controlled substance is identified, the possibility exists that an individual could be imprisoned or suffer some other legal consequence as a result. There is, therefore, an absolute, uncompromised requirement for certainty in the identification of controlled substances. Prior to 1960, the results of microscopic crystal tests, color screening tests, and TLC were considered definitive. From the 1960s through the mid-1970s, UV spectrophotometry and GC gained acceptance. It is interesting to look back 30 years and contemplate the absolute faith placed in a retention time on a gas chromatogram, or upon the UV absorption maxima in acidic or basic solutions. In some instances these numerical values were measured with a ruler!

From 1975 through 1985 there were major advances in IR and MS. During those years “specificity,” as we understand the term today, was, for the first time, actually attainable in most cases. As the technology continually evolved, with increased Fourier transform peak resolution in IR and NMR, and multicomponent separations improved with capillary column GS, specificity also increased.

In the mid-1980s the advent of “designer drugs” (properly referred to as “controlled substance analogues”) resurrected the problem of specificity. In attempts at circumventing existing controlled substance laws, clandestine laboratory chemists began to alter chemical structures of controlled drugs by increasingly sophisticated syntheses. By replacing a methyl group with an ethyl group, or by using a five-membered ring instead of a six-membered ring in a synthesis, these clandestine laboratory chemists developed what at the time were non-controlled analogues. The Controlled Substance Analogue and Enforcement Act of 1986 was passed by Congress, largely as a response to this problem. This particular piece of legislation also reinforced the responsibility of the chemist to accurately discriminate between controlled substances and endless lists of possible analogues.

A direct consequence of the new law’s passage was the development of analytical procedures in Fourier transform infrared spectrophotometry (FTIR), Fourier transform nuclear magnetic resonance spectroscopy (FTNMR), gas chromatography/Fourier transform infrared spectroscopy (GC/FTIR), and CE. These instrumental methods have made their way into the forensic science laboratory and now provide the increased specificity required by the courts.

Controlled substances sold on the street are usually mixed with adulterants and diluents in a crude and mostly unspecified manner. In some laboratories, analysts are required to identify and quantitate both the controlled substance and the adulterant drugs and diluent materials. Color tests, TLC, and microcrystal tests of the pre-1960s vintage are still used for screening. These testing procedures were valid then and are still valid today, but today additional instrumental techniques are utilized to make the absolute identification and quantitation.

After the analysis has been completed, it must be documented. The final report must be clear, concise, and accurate, with all conclusions substantiated by analytical data. The data may be in the form of notations on paper in the analyst’s writing, or on chromatograms, spectra, or other instrumental printouts. Dates must be checked, and the documented description of the exhibit(s) must be consistent with the actual exhibit. Each time a report is signed, the analyst places his or her reputation and credibility before the scrutiny of the court and his or her peers. Discovering a “mistake” after the report has been submitted to the courts is not good.

Cocaine can exist as either the hydrochloride (HCl) salt or as the base. Pursuant to federal law, there are sentencing guidelines based on the identification of cocaine as either the base or as the

salt form (usually HCl). Cocaine can be adulterated with benzocaine, procaine, lidocaine, or any combination of these non-controlled drugs, and further diluted with mannitol, lactose, or other processing sugars. A variety of instrumental techniques can be used to distinguish cocaine HCl from cocaine base. FTIR spectrophotometry is commonly available and used in many laboratories. The IR spectra of cocaine HCl and cocaine base are quite different and easily distinguished. The IR spectrum of a cocaine HCl sample mixed with an adulterant presents a problem. The same sample analyzed by GC/FTIR presents the chemist with a total response chromatogram showing all peaks in a mixture. The resulting IR spectrum and mass spectrum are identifiable. However, in this technique, cocaine HCl and cocaine base cannot be distinguished. At this point, NMR can provide a solution to distinguishing the two forms of cocaine and identifying the adulterants.

The solubility properties of controlled substances can be used to separate different forms of controlled substances. For instance, cocaine base is soluble in diethyl ether; cocaine HCl is insoluble. Therefore, if an analyst is analyzing a material that is believed to be cocaine in a questionable form, the analyst can try placing the material into solution with diethyl ether, separate the ether from the insolubles, evaporate the diethyl ether, and analyze the resulting powder by GC/MS. The resulting cocaine spectrum would indicate the presence of cocaine base because cocaine HCl would not have gone into solution.

Methamphetamine is produced in clandestine laboratories from the reaction of ephedrine with hydriodic acid and red phosphorus, or from the reaction of phenyl-2-propanone (P-2-P) with methylamine. Methamphetamine samples submitted to the forensic science laboratory usually contain precursors from the synthesis, by-products for side reactions, and adulterants such as nicotinamide that have been added by the clandestine laboratory operator. As is true of the mass spectrum of some other phenethylamines, the mass spectrum of methamphetamine may not provide enough specificity for positive identification. The most accurate way to identify many phenethylamines is with IR. However, NMR is at least as specific as FTIR, and it also allows for an identification in the presence of diluents. Unfortunately, NMR is not available in many laboratories. Nicotinamide is one of the more commonly encountered adulterants with methamphetamine and can easily be distinguished from isonicotinamide by NMR spectroscopy.

The IR spectrum of methamphetamine hydrochloride in a potassium chloride salt matrix is very specific, and GC/FTIR is excellent at separating the components of a methamphetamine sample. However, this method requires great care in selecting the optimized temperature and flow parameters, and column selection.

GC/MS is the method most often used for identifying heroin. The mass spectrum of heroin is very specific. Heroin is relatively simple to separate, and identification of the degradation products and the by-products of the heroin synthesis, from morphine and acetic anhydride, is relatively straightforward. Because morphine is derived from opium, many of the by-products from the opium processing are carried over to the final heroin product. Acetylcodeine and acetylmorphine are clearly identified from the corresponding mass spectra. The GC/FTIR also provides excellent spectra for making identifications of heroin, its by-products, degradation products, and precursors. The chloroform insoluble diluents from heroin samples can also be identified in a potassium bromide matrix by FTIR. These materials will usually consist of sugars such as mannitol and inositol. When the heroin has been isolated from diluents and adulterants, FTIR and NMR can be utilized to confirm the salt form of the heroin.

Phencyclidine, more properly identified as phenylcyclohexylpiperidine (PCP), is usually submitted to the laboratory as an exhibit of PCP base in diethyl ether, a powder, or sprayed or coated on marijuana. The analysis of PCP is relatively direct by GC/MS. The resulting mass spectrum is specific. The GC/FTIR spectrum of PCP is not as specific when one compares this spectrum with that of PCP analogues and precursors such as phenylcyclohexyl carbonitrile (PCC) and phenylcyclohexyl pyrrolidine (PCPy). FTIR spectrophotometry of the solid in a potassium bromide matrix is very specific. A word of caution is in order for anyone handling PCP. PCP is a substance that is believed to be easily absorbed through the skin of the analyst. Minimum handling is recommended.

1.7.3.2 Identifying Adulterants and Diluents

The terms *adulterants* and *diluents* are sometimes used in the context of illicitly distributed controlled substances. Adulterants are chemicals added to illicit drugs that, in and of themselves, can affect some sort of a physiological response. This response can range from very mild to quite severe. Diluents are chemicals added to controlled substances that are used more as fillers than to elicit a physiological response. They can be added to affect the color and composition for the sake of satisfying the user. Adulterants and diluents are usually added to the controlled substance mixture by those involved in illicit distribution. There is a third class of materials that is found in controlled substance mixtures. This class includes by-products. These by-products can be processing by-products, or they can exist as naturally occurring by-products found in botanical substances such as the coca leaf or the opium poppy.

Most “street” exhibits of heroin and cocaine contain adulterants and diluents. Samples taken from large-scale, brick-size, kilogram seizures will be relatively pure. Except for some by-products from the opium poppy and the coca leaf, there will be little in the way of foreign materials. Adulterants are encountered, in increasing proportions, as the heroin and cocaine progress down the distribution chain from the main supplier to the dealers to the users.

Adulterants commonly encountered in heroin include quinine, procaine, acetaminophen, caffeine, diphenhydramine, aspirin, phenobarbital, and lidocaine. Adulterants commonly encountered in cocaine include procaine, benzocaine, and lidocaine. Diluents found in heroin include different kinds of starches. It is not uncommon to find in heroin substances, such as calcium carbonate, that had been added during the morphine extraction processes. Diluents found in both cocaine and heroin include lactose, mannitol, sucrose, and dextrose.

The identification of adulterants and diluents may or may not be a requirement as a part of the identification scheme in the forensic science laboratory. In most instances, the requirements of the judicial system will be limited to the identification of the controlled substance. This will usually be accomplished by separating the sample into its component parts, and then identifying all or some of these components. In the case of a heroin exhibit, cut with quinine and mannitol, a capillary GC/MS examination might result in a chromatogram and corresponding spectra with an acetylcodeine peak, an acetylmorphine peak, a morphine peak, a quinine peak, and a heroin peak. The first two peaks are most probably processing by-products; the morphine is from the opium poppy; the heroin is the main peak of interest, and the quinine has probably been added as an adulterant. There is no need to separate the components by extractions to make the identifications. However, if the analyst is desirous of conducting an IR examination or a NMR examination to identify the heroin, an extraction of the heroin from a 3 *N* hydrochloric acid medium using chloroform is an option. Depending on whether the heroin exists as a salt (heroin hydrochloride) or as heroin base, a set of serial extractions can be conducted to isolate the heroin from the quinine and the other substances. The identification of cocaine in a mixture follows the same procedures. Depending on the type of analysis, the cocaine may or may not need to be chemically separated from the adulterants for an identification.

The simplest way to identify diluents in controlled substance mixtures is by microscopic identification. Common diluents along with the sugars/carbohydrates/starches described above include sodium chloride, calcium carbonate, and various types of amorphous materials. Because of their optical properties, these materials lend themselves well to a microscopic identification. Chemical separations are fairly easy because these materials are usually insoluble in solvents such as diethyl ether or hexane, and slightly soluble in solvents such as methanol. Most organic materials are soluble in methanol or some other polar solvent. The sugars/carbohydrates/starches can be further identified using IR following the separation if only one sugar is present. If not, HPLC can be used to identify the sugars.

Even if the identification of all adulterants, diluents, and by-products is not required in the final report generated by the analyst, such information can prove useful in evaluating trends and possible distribution patterns.

1.7.3.3 Quantitating Controlled Substances

A number of different methods can be used to quantitate controlled substances. Capillary column GC or HPLC are probably the two most utilized instrumental methods to accomplish this task. The choice of which instrumental method to use depends on the chemical properties of the substance in question. GC works well with those compounds that are not highly polar, are relatively stable at high temperatures, and are soluble in organic solvents such as methanol or chloroform. Even if these conditions exist, GC can still be used if a derivatizing agent is used.

If GC is used, the most common analytical method for quantitation involves the use of an internal standard, providing a consistent concentration of a known chemical in solution. To avoid the obvious problem of choosing an internal standard, which might be present in the sample as an adulterant or diluent, the internal standard can be a straight-chain hydrocarbon (tetracosane, eicosane, or dodecane) that is added in equal amounts to both the sample being analyzed and the calibration samples. The internal standard method is especially advantageous because the expected flame ionization detector response for the internal standard to the drug can be checked for each and every injection. The critical factor for each injection is the ratio of the detector response of the internal standard to the calibration solution of known concentration. This is especially critical if the sample size of the injection is off target by a minuscule amount. The absolute integration values for the known peak and the internal standard peaks may vary. However, the ratio will not be affected. If the detector is responding properly to the internal standard in solution, it is also responding properly for the substance being quantitated.

Controlled substances can also be quantitated using what is referred to as the external standard method. In this method, calibration standards of known concentrations are prepared. Injections are then made into the GC injection port, and a calibration table is established. The accuracy of this method is quite good, provided that the injection amounts used in establishing the calibration table are exactly the same from injection to injection. Even small variations of less than 10% volume, when dealing with a 1- μ l injection, can lead to less than optimized results. This problem can be overcome by making multiple injections and checking the consistency of the detector response and the injection volume. The ability to be consistent can be developed by an analyst with a good eye. The ability to read the sample size on the microsyringe is, for some, as much an art as a scientific technique. Automatic injectors are now available on many gas chromatographs, which approach consistency from one injection to the next. However, this method will work only when there is a verifiable linear response of the detector within a specified concentration range.

In both the internal and external standard methods, there must be a linear response of the detector to the solutions of different concentrations. This is determined by injecting solutions of known concentrations and establishing a calibration table. With most instrument data stations, this is relatively simple. The instrument will then calculate the response ratio of internal standard to drug for the solution of unknown concentration and compare this to the response ratios of internal standard to drug for the solutions of known concentrations in the calibration table. This ratio can then be used to calculate the concentration of the drug that is being analyzed.

HPLC can be useful for quantitating controlled substances in solution. This instrumental method also measures the response of different compounds at different ultraviolet/visible absorption bands. These responses are then compared to calibration table values. Internal standards can be used in the same way they are used in GC quantitations. The limitations and comparisons of HPLC and GC are discussed elsewhere.

Ultraviolet/visible spectrophotometry (UV/VIS) is a technique that has been in use for many years. UV/VIS uses one of the basic tenets of physics — Beer's law. Absorption of monochromatic light is proportional to the concentration of a sample in solution. The concentration of an exhibit in solution can be determined by comparison with calibration tables. This type of analysis is dependent on the solubility properties of the substance being quantitated in acid, basic, and organic solutions. The UV/VIS method is accurate and reliable only when the compound of interest is pure with no interfering substances. GC and HPLC are used more often because of the added reliability check provided by the internal standard methodology.

NMR spectrometry can also be used for the quantitation of controlled substances. The quantitative analytical techniques in NMR are more complicated than those discussed above and require a specialized instrumental expertise.

All of the methods discussed are reliable and accurate when properly and conscientiously conducted. There is one very important difference that applies to any quantitative method when compared to an identification method. With proper methods, an analyst can make an identification of a controlled substance with scientific certainty. The quantitation of a controlled substance will usually result in values falling within a narrowly defined "window" of from one-tenth to one or two absolute percent. The reported value will usually be an average value.

1.7.3.4 Reference Standards

The first step in ensuring the accuracy of the identification of any controlled substance should be a collection of authenticated reference standards. Reference standards for the forensic science examinations should be 98+% pure. They can be purchased from a reputable manufacturer or distributor, synthesized by an organic chemist within the laboratory, or purified from a bulk secondary standard by using an appropriate methodology. "Reference Standards" that have been authenticated are available from the United States Pharmacopoeia (USP) and National Formulary (NF). Samples obtained from any other source should be authenticated using the appropriate methodology. This authentication process will involve a two-step process of first positively identifying the proposed reference standard and then determining the purity of this standard.

At a minimum, the identification of a reference standard should be conducted using IR and MS. The resulting spectra are then compared with reference spectra in the literature. The chemist should be able to evaluate data from both of these instruments and be able to explain the major peaks using, respectively, a functional group analysis or a molecular fragmentation analysis. If no literature spectra are available, a more sophisticated structural analysis such as NMR spectroscopy will be necessary to verify the chemical structure. Additional methods that can be used to supplement, but not replace, IR, MS, and NMR include optical crystallography, X-ray crystallography, and a melting point analysis.

The next step in the process is to quantitate the reference standard against a "primary standard." A primary standard is a sample that has been subjected to the authentication process and meets the criteria of a positive identification and 98+% purity. The quantitation methods of choice are GC or HPLC. With either method, the concentrations of the injections of both the primary standard and the authentication sample must be within the linear range of the detector. The method should utilize an internal standard. The results of all injections should have a relative standard deviation of less than 3%.¹

If a primary standard is not available, a purity determination can be accomplished by a peak area percent determination using capillary GC with a flame ionization detector and HPLC using a photo-array ultraviolet detector. A third instrumental method using a differential scanning calorimeter (DSC) should also be considered. In a peak area percent analysis, the area percent of the standard compound is determined vs. any impurities that are present in the batch. A blank injection of the solvent is done prior to the standard injection to detect peaks common to both

the solvent and the authentication standard. The GC solution is checked for insolubles. If these insolubles are present, they can be isolated and identified by IR. Of course, if there are insolubles, the sample is no longer considered an authentication standard until it is purified and the foreign material is removed.

HPLC can also be used in a peak area percent analysis. For basic drugs, the analyst would use a gradient mobile phase using methanol and an acidic aqueous phosphate buffer. For neutral and acidic drugs, he would use a gradient with methanol and an acidic aqueous phosphate buffer containing sodium dodecyl sulfate. For anabolic steroids, he would use a methanol/water gradient mobile phase. As is the case with GC, with HPLC a blank injection of the solvent always precedes the injection of the authentication standard. Three wavelengths, 210 nm, 228 nm, and 240 nm, are monitored for most drugs. For anabolic steroids, the analyst should monitor 210 nm, 240 nm, and 280 nm. If the resulting UV spectra of all pertinent peaks are similar, the integration of the peaks with the most sensitive wavelengths are used for the calculation of purity.

DSC is a method of adding heat to a preweighed sample and monitoring temperature and heat flow as the sample goes through its melting point.² If decomposition does not occur during the melt, the peak shown on the thermogram can be used to determine melting point and the molar concentration of any melt soluble impurities present. With these data, the analyst can determine the purity of the authentication standard. One drawback of DSC is that structurally dissimilar impurities such as sugars in a supposed heroin “standard” are not always detected by this method. This is because the impurity does not go into solution in the melting main component. With almost all authentication standards, most impurities will be structurally similar to the drug of interest. The dissimilar compounds should have been removed prior to the DSC analysis or detected by GC or HPLC.

1.8 COMPARATIVE ANALYSIS

1.8.1 Determining Commonality of Source

Two different kinds of controlled substance analyses are routinely conducted in the forensic science laboratory. The first is the “identification.” The goal is self-evident — to identify a controlled substance by name. The second, less common, type of analysis is the “comparative analysis.” Its purpose is to determine a commonality of source. A comparative analysis will include a comprehensive examination of the sample’s chemical and physical characteristics, with the goal of demonstrating, with a high degree of certainty, a common origin for two or more samples.¹

Sometime it is possible to determine when two items of evidence have a common origin just by physically fitting them together. This applies to exhibits such as a screwdriver and a broken blade, two large paint chips that have broken apart, or a piece of paper torn in two or more pieces. In the forensic examination of illicit drugs, it is possible to state with a high degree of certainty that two exhibits of a white powder share a common source. The wording in stating such a conclusion is critical. Words must be carefully selected to convey the conclusion clearly and concisely, without overstepping the scientific certainty that exists. The following quote, about two samples of cocaine, is from the transcript of drug trial held in 1991. It illustrates the appropriate language to be used on such occasions.

After a review of all analytical data, it can be stated with a high level of scientific certainty and beyond a reasonable doubt that a close chemical relationship exists between [the two samples] strongly suggesting that they were derived from the same manufacturing process ... and that they were probably derived from the same batch.²

Before undertaking a detailed examination of two samples, a broad overview is desirable. The color and granularity of the exhibits should be examined, and then the components of the sample identified and quantitated. If all of the data from one exhibit compare favorably with all of the data from the second exhibit, the analyst can proceed to a second set of procedures to evaluate the processing by-products and trace materials in the exhibits. It is important to realize that to successfully evaluate two exhibits to determine commonality of source, each exhibit must be analyzed in the same way using the same methodology, instruments, and chemicals and solvents from the same containers.

Controlled substances such as cocaine and heroin are the simplest to compare because they are derived from botanical substances (the coca leaf and the opium poppy, respectively).^{3,4} Many naturally occurring by-products from the plants are carried through the processing stages of the drugs, and these can be used to confirm the existence of a common source.

1.8.2 Comparing Heroin Exhibits

Capillary column gas chromatography (ccGC) and HPLC are the two methods most often utilized in comparing two or more heroin exhibits to determine whether they came from the same source. HPLC can be utilized in the first part of the analytical scheme because the components being evaluated usually are present in substantial amounts. The major components, including heroin, acetylmorphine, acetylcodeine, morphine, codeine, noscapine, papaverine, thebaine, and most diluents can be identified and quantitated. A high degree of resolving power is not required at this point in the analytical scheme. If the HPLC analysis demonstrates that the samples being compared are similar, the analyst proceeds to the second part of the analytical scheme.

In the second part of this scheme to evaluate the trace components of the exhibits, ccGC is usually the method of choice, both because of its resolving power and because of its ability to detect minute quantities of the component of interest. The second step of the isolation process involves multiple extractions and derivatizations to isolate the acidic and neutral compounds for analysis and evaluation. This process isolates the precursors, solvents, and respective contaminants, by-products, intermediates, and degradation products. It is desirable to remove the heroin from the sample during the extraction processes in order to keep most of the trace components at the same level of chromatographic attenuation. Once the heroin has been identified and quantitated, only then are the other elements analyzed. If after these two processes the analyst sees no chromatographic differences in the samples being evaluated, a conclusion can be formulated. The number of components from this second part of the process can number from 100 to 300. If all of these components are present in both exhibits at similar relative levels, a conclusion regarding commonality of source is warranted.

1.8.3 Comparing Cocaine Exhibits

The process is different for cocaine comparisons. For one thing, the cocaine need not be removed from the sample. Four different ccGC examinations can be conducted that evaluate and compare the by-products and impurities down to trace levels by:

1. Flame ionization gas chromatography (GC-FID) to evaluate cocaine hydrolysis products, manufacturing impurities, and naturally occurring alkaloids⁵

2. GC-FID to determine trimethoxy-substituted alkaloids as well as other minor naturally occurring tropanes⁶
3. Electron capture gas chromatography (GC-ECD) to determine the hydroxycocaines and N-nor related compounds⁴
4. GC-ECD to determine the ten intact truxillines⁷

These four gas chromatographic methods provide an in-depth evaluation of trace level components and allow the precise comparison of two different cocaine exhibits. The number of components evaluated ranges in the hundreds. These data provide the analyst with an abundance of analytical points to form a conclusion regarding commonality of source.

Extraction of the impurities and by-products can be accomplished using a derivatizing reagent.^{8,9} Heptafluorobutyric anhydride (HFBA) is often used for this purpose. The GC-FID and GC-ECD analyses that follow will result in organic profiles of the many compounds from the cocaine and heroin samples being analyzed. A further MS analysis may serve to identify the chemical composition of many of the components of each exhibit. Many of the resulting peaks represent compounds formed during the manufacturing process; others will be oxidation or hydrolysis products of known compounds; and other peaks will have a degree of uncertainty regarding their exact chemical structure. However, what will be known is that these peaks are present in both exhibits being compared using the ccGC methods and represent cocaine and heroin manufacturing impurities or by-products.

1.9 CLANDESTINE LABORATORIES

There are two kinds of clandestine laboratories. The first is the **operational** clandestine laboratory. This laboratory, usually operating in secrecy, is engaged in the production of controlled substances, precursors to controlled substances, or controlled substance homologues or analogues. The second

is the **non-operational** clandestine laboratory. This usually is a storage facility that is under investigation because of information obtained from precursor and essential chemical monitoring.¹

For the forensic scientist involved in the seizure of a clandestine laboratory, the task of evaluating the possibilities and probabilities begins prior to arrival at the laboratory site. The individual tasked with securing the laboratory for the purpose of collecting evidence must, for his own protection, be trained and certified competent in dealing with the safety and technical considerations of clandestine laboratory seizures. Forensic chemists may be asked to provide assistance in preparing search warrants based on available information, as when investigators know that certain chemicals and pieces of analytical equipment such as gas cylinders, and glassware such as large triple neck round bottom flasks have been purchased. This sort of information is critical in determining what kind of synthesis is taking place. The forensic scientist will also provide technical advice regarding the importance of specific safety considerations and offer suggestions on handling situations such as on-going reactions.

After the clandestine laboratory site has been secured by the appropriate law enforcement authorities, the forensic scientist may enter the site to evaluate the environment and decide on the most appropriate actions. The investigator's most important function is to minimize any health risk to enforcement personnel. This may involve ventilating the environment by opening doors, windows, and using a fan; securing open containers, turning off gases and water; and removing obstacles on the floor, which may prove hazardous to anyone entering the site. The investigator may also decide on whether chemical reactions in progress should be stopped or allowed to proceed. After all of these and other decisions are made and the site is secure, the forensic analyst will begin to sample, package, and mark evidence containers. This process will usually proceed slowly and methodically to ensure accuracy and completeness.

Once the clandestine laboratory has been seized and the evidence collected, the forensic analyst will proceed to the laboratory to complete the administrative processes of ensuring accountability and security. When the time approaches for the analytical procedures to commence, the person tasked with this process will attempt to identify as many of the samples as deemed necessary for the required judicial action. This may mean identifying any and all exhibits that were seized, or it may mean that only those exhibits required to form a conclusion regarding an identification of the final product are necessary. The extent of the analysis can be more of a legal question than a scientific question. The forensic scientist should be able to provide the basics of the reaction mechanisms. This information will be based on the chemicals at the site and those identified in the reaction mixtures. He should also be able to provide a theoretical yield of the final product based on the amounts of the chemical precursors.

After the work in the laboratory has been completed, the forensic scientist has the responsibility of assisting the legal authorities in understanding what was happening in the clandestine laboratory — what was being synthesized, how was it being synthesized, and what environmental ramifications existed due to the disposing of waste solvents and other chemicals found in the soil or plumbing. The forensic analyst must recognize his responsibilities as an expert witness and provide factual information in as much detail as necessary. However, this task carries with it the responsibility of avoiding unsubstantiated speculation.

Evaluating a clandestine laboratory, from the time of notification until the time of testimony in the courtroom, requires an open-minded and analytical approach. As information is gathered and data collection proceeds, the analyst may be involved in an ever-evolving decision-making process. This will probably require him to change his strategies as more information becomes available. Conclusions should be reserved until all the necessary exhibits have been collected and analyzed, the clandestine laboratory operator has been debriefed, the analytical data have been evaluated, and, if necessary, consultations with colleagues have been completed. In the courtroom, the forensic analyst will preserve his status as a credible expert witness by basing his testimony on factual data and possibilities that are within the realm of scientific probability.

1.9.1 Safety Concerns

A hazard evaluation is an absolute requirement prior to entering a clandestine laboratory. This should involve an evaluation of the physical and environmental hazards that may be present. This evaluation is usually the result of questioning other law enforcement personnel familiar with the laboratory, or the laboratory operator. Great care should be exercised in evaluating and acting on information from the laboratory operator. The forensic analyst should determine the minimum level of safety equipment required for entry into the laboratory. If there is knowledge regarding the type of drug being synthesized in the clandestine laboratory and the processing methodology, the forensic scientist will have some idea about the types of chemicals that may be encountered. If records are available regarding the purchasing activity of the clandestine laboratory operator, the quantities of the chemicals facing the investigators will be available.

All this information should be documented and used to decide the safest and most prudent manner in which to enter the clandestine laboratory. Other concerns that must be considered are the weather conditions, and entry and egress options. Extremes in either heat or cold can affect the way the safety and sampling equipment will function. These conditions will also affect how long the forensic chemist can be expected to work in the appropriate clothing. Egress options from a clandestine laboratory must be determined before entry. In the event of a fire or explosion, those individuals processing the clandestine laboratory must know how to exit the dangerous environment. As a part of the planning scenario for processing the clandestine laboratory, the appropriate authority should make the nearest medical facility aware of the fact that if an investigator is injured, medical attention will be sought. The medical facility may have some requirement for treating a chemical injury. This should be determined beforehand and a protocol to meet these requirements should be established.

The most important responsibility of the forensic analyst involved in a clandestine laboratory investigation and seizure is safety. Safety must be considered from a number of perspectives. The forensic scientist must be concerned with the safety and well-being of anyone entering the suspected clandestine laboratory. His training and experience will have prepared him to recognize many of the obvious dangers of the chemical hazards and physical hazards at the site. This awareness is not stagnant. There will usually be a condition that requires an immediate adjustment and reevaluation. He must be constantly aware of the possible hazards when the combination of two minimally unsafe conditions result in fatalities. This results from a failure to recognize that while each condition is dangerous in its own right, combining the dangers is a recipe for disaster if certain precautions are not followed.

For instance, if the odor of ether is detected in an enclosed dark room, a possible first step might be to turn on the lights. However, any short circuit in the light switch resulting in a spark could cause the ether vapors in combination with the oxygen in the air to explode. The correct action would be to obtain outside lighting equipment to determine the source of the ether vapors, rectify the conditions resulting in the ether vapors, ventilate the room, check the light switch and wiring, and then turn on the lights. This situation is one in which a chemical hazard and a physical hazard could combine and result in serious injury or death.

Before entering the clandestine laboratory, the forensic analyst must take precautions to ensure eye, lung, and skin protection. This will usually mean proper clothing including head gear, boots, outerwear, and gloves; safety glasses and/or a face shield; and the appropriate air purification and breathing apparatus. Consideration should also be given to use of air-monitoring devices, which can detect concentrations of combustible gases or vapors in the atmosphere, oxygen deficiencies, and gas concentrations to lower explosive limits. There are also devices available in the form of glass tubes filled with specific detection granules, which allow for the reasonable determination of airborne chemical hazards in the atmosphere. When these devices are used properly, the forensic scientist entering the clandestine laboratory maximizes his chances for protecting the safety of the seizure team, including himself.

Even after the atmosphere has been sampled and ventilation has progressed, once inside the clandestine laboratory, the forensic chemist should be aware of the many possibilities posing a threat. The potential chemical dangers include an explosion potential, flammable and combustible chemicals, corrosive chemicals, oxidizers, poisons, compressed gases, irritants, and booby traps. Physical hazards include but are certainly not limited to broken glass, bare electrical wiring, slippery floors, and loud noises. These chemical and physical hazards can be accentuated by a reduction in dexterity because of safety equipment and clothing, a narrow field of vision due to a breathing apparatus, diminished communications, physical and mental stress, heat or cold stress, a confined work space environment, and a prolonged period of time spent processing the clandestine laboratory.

After the laboratory processing has been completed, the forensic scientist should be a part of the team that reduces the level of environmental contamination to a controllable level. This will usually involve prior planning for the proper disposal of hazardous chemicals and protective clothing by a waste disposal authority. There should be a standard operating procedure for the decontamination of anyone who entered the clandestine laboratory. This should include provisions for an emergency shower and an eyewash station, first aid kits, and decontamination procedures for injured workers.

One of the most important factors anyone processing a clandestine laboratory must remember is the following: no matter how much protective clothing is available, no matter how much pre-planning is done, no matter how careful a person might be in collecting chemicals and assessing danger, if that person fails to recognize his or her limitations in knowledge or physical ability, a disaster is waiting to happen. The greatest danger facing anyone who processes a clandestine laboratory is a false sense of security.

1.9.2 Commonly Encountered Chemicals in the Clandestine Laboratory

The following tabulation of data is intended as an overview of those chemicals most frequently encountered as precursors in clandestine laboratory settings. A **precursor** is a chemical that becomes a part of the controlled substance either as the basis of the molecular skeleton or as a substituent of the molecular skeleton. This list is not all-inclusive. Modifications to typical synthetic routes on the parts of ingenious organic chemists are typical and cannot always be predicted.

Precursor	Controlled Substance
Acetic anhydride	Heroin Methaqualone Phenyl-2-Propanone (P2P)
Acetonitrile	Amphetamine
N-Acetylanthranilic acid	Methaqualone Mecloqualone
Acetylacetone	Methaqualone
4-Allyl-1,2-methylenedioxybenzene	3,4-Methylenedioxyamphetamine (MDA)
Ammonium formate	Amphetamine MDA
Amphetamine	alpha-Methyl fentanyl
Aniline	alpha-Methyl fentanyl
Anthranilic acid	Methaqualone
Benzaldehyde	Amphetamine P-2-P
Benzene	Amphetamine P-2-P
Benzyl cyanide	Methamphetamine
Bromobenzene	N-Ethyl-1-phenylcyclohexylamine (PCE) Phencyclidine (PCP) 1-Phenylcyclohexylpyrrolidine (PCPy) P-2-P

Precursor	Controlled Substance
1-Bromo-2,5-dimethoxybenzene	4-Bromo-2,5-dimethoxyamphetamine (DOB)
Bromohydroquinone	DOB
5-Bromoisatin	Lysergic acid
ortho-Bromophenol	4-Bromo-2,5-dimethoxyphenethylamine (Nexus)
Bromosafrole	3,4-Methylenedioxyethylamphetamine (MDEA)
	3,4-Methylenedioxymethamphetamine (MDMA)
2-Bromothiophene	1-[1-(2-Thienyl)cyclohexyl]piperidine (TCP)
Chloroacetic acid	P-2-P
Chloroacetone	P-2-P
1-Chloro-2,5-dimethoxybenzene	Nexus
2-Chloro- <i>N,N</i> -dimethylpropylamine	Methadone
2-Chloroethylbenzene	Fentanyl
alpha-Chloroethylmethyl ether	P-2-P
Chlorohydroquinone	DOB
Chlorosafrole	MDEA
	MDMA
ortho-Cresol	4-Methyl-2,5-dimethoxyamphetamine (STP)
Diethylamine	Diethyltryptamine
	Lysergic acid diethylamide (LSD)
Ephedrine	Methamphetamine
	Methcathinone
Ergonovine	LSD
Ergotamine	LSD
Ethylamine	Ethylamphetamine
	3,4-Methylenedioxyethylamphetamine (MDEA)
<i>N</i> -Ethylephedrine	<i>N</i> -Ethyl- <i>N</i> -methylamphetamine
<i>N</i> -Ethylpseudoephedrine	<i>N</i> -Ethyl- <i>N</i> -methylamphetamine
ortho-Ethylphenol	4-Ethyl-2,5-dimethoxyamphetamine
Formamide	Amphetamine
	MDA
Hydroxycodone	Oxycotin
Isosafrole	4-Methylenedioxyamphetamine (MDA)
	3,4-Methylenedioxymethamphetamine (MDMA)
	MDEA
Lysergic acid	LSD
Methylamine	Methamphetamine
	MDMA
3,4-Methylenedioxyphenyl-2-propanone	MDA
	MDMA
	MDEA
<i>N</i> -Methylephedrine	<i>N,N</i> -Dimethylamphetamine
<i>N</i> -Methylpseudoephedrine	<i>N,N</i> -Dimethylamphetamine
Nitroethane	P-2-P
	Amphetamine
	MDA
1,2-Methylenedioxy-4-propenylbenzene	MDEA
<i>N</i> -Methylephedrine	P-2-P
<i>N</i> -Methylformamide	Methamphetamine
<i>N</i> -Methylformanilide	STP
2-Methyl-4-[3H]-quinazolinone	Methaqualone
Methyl-3,4,5-trimethoxybenzoate	Mescaline
Norpseudoephedrine	4-Methylaminorex
Phenethylamine	Fentanyl
	para-Fluoro fentanyl
	2-Methyl fentanyl
<i>N</i> -(1-Phenethyl)-Piperidin-4-one	Fentanyl
	para-Fluoro fentanyl
<i>N</i> -(1-Phenethyl-4-piperidinyl)-aniline	Fentanyl
Phenylacetic acid	P-2-P

Precursor	Controlled Substance
Phenylacetonitrile	P-2-P
Phenylacetyl chloride	P-2-P
D-Phenylalanine	Amphetamine
	Methamphetamine
2-Phenyl-1-bromoethane	Fentanyl
1-Phenyl-2-bromopropane	alpha-Methyl fentanyl
Phenylmagnesium bromid	PCP
	PCPy
	P-2-P
Phenylpropanolamine	Amphetamine
	4-Methylaminorex
Phenyl-2-propanone (P-2-P)	Amphetamine
	Methamphetamine
Piperidin	Phencyclidine (PCP)
N-(4-Piperidiny)aniline	Fentanyl
	alpha-Methyl fentanyl
Piperonal	MDA
	MDMA
	MDEA
Piperonylacetone	N-Hydroxy MDA
Propionic Anhydride ¹	Fentanyl analogues
Propiophenone	Methamphetamine
Pyrrolidine	PCPy
Pseudoephedrine	Methamphetamine
Safrole	MDA
	MDMA
	3,4-Methylenedioxy P-2-P
3,4,5-Trimethoxybenzaldehyde	Mescaline
	3,4,5-Trimethoxyamphetamine

1.9.3 Tables of Controlled Substances

1.9.3.1 Generalized List by Category of Physiological Effects and Medical Uses of Controlled Substances

Controlled Substances — Categorized Listing of the Most Commonly Encountered Controlled Substances

Drug	CSA Schedules	Trade or Other Names	Medical Uses
Narcotics			
Heroin	I	Diacetylmorphine, Horse, Smack	None in U.S., analgesic, antitussive
Morphine	II	Duramorph, MS-Contin, Roxanol, Oramorph SR	Analgesic
Codeine	II, III, IV	Tylenol w/Codeine, Empirin w/Codeine, Robitussin A-C, Fiorinal w/Codeine, APAP w/Codeine	Analgesic, antitussive
Hydrocodone	II, III	Tussionex, Vicodin, Dycodan, Lorcet	Analgesic, antitussive

Controlled Substances — Categorized Listing of the Most Commonly Encountered Controlled Substances (Continued)

Drug	CSA Schedules	Trade or Other Names	Medical Uses
Hydromorphone	II	Dilaudid	Analgesic
Oxycodone	II	Percodan, Percocet, Tylox, Roxicet, Roxidone	Analgesic
Methadone and LAAM	I, II	Dolophine, Levo-alpha-acetylmethadol, Levomethadyl acetate	Analgesic, treatment of dependence
Fentanyl and analogues	I, II	Innovar, Sublimaze, Alfenta, Sufenta, Duragesic	Analgesic, adjunct to anesthesia, anesthetic
Other narcotics	II, III, IV, V	Percocan, Percocet, Tylox, Opium, Darvon, Talwin, ^a Buprenorphine, Meperidine (Pethidine)	Analgesic, antidiarrheal
Depressants			
Chloral hydrate	IV	Noctec, Somnos, Felsules	Hypnotic
Barbiturates	II, III, IV	Amytal, Fiorinal, Membutal, Seconal, Tuinal, Penobarbital, Pentobarbital	Sedative hypnotic, veterinary euthanasia agent
Benzodiazepines	IV	Ativan, Dalmane, Diazepam, Librium, Xanax, Serax, Valium, Tranxene, Verstran, Versed, Halcion, Paxipam, Restoril	Antianxiety, sedative, anticonvulsant, hypnotic
Glutethimide	II	Doriden	Sedative, hypnotic
Other depressants	I, II, III, IV	Equanil, Miltown, Noludar, Placidyl, Valmid, Methaqualone	Antianxiety, sedative, hypnotic
Stimulants			
Cocaine ^b	II	Coke, Flake, Snow, Crack	Local anesthetic
Amphetamine/methamphetamine	II	Biphedamine, Desoxyn, Dexedrine, Obetrol, Ice	Attention-deficit disorder, narcolepsy, weight control
Methylphenidate	II	Ritalin	Attention-deficit disorder
Other stimulants	I, II, III, IV	Adipex, Didrex, Ionamin, Melfiat, Plegine, Captagon, Sanorex, Tenuate, Tepanil, Prelu-2, Preludin	Weight control
Cannabis			
Marijuana	I	Pot, Acapulco Gold, Grass, Reefer, Sinsemilla, Thai Sticks	None
Tetrahydro-cannabinol	I, II	THC, Marinol	Antinauseant
Hashish and hashish oil	I	Hash, Hash Oil	None
Hallucinogens			
LSD	I	Acid, Blotter Acid, Microdots	None
Mescaline and peyote	I	Mescal, Buttons, Cactus	None
Phenethylamines	I	2,5-DMA, STP, MDA, MDMA, Ecstasy, DOM, DOB	None
Phencyclidine and analogues	I, II	PCP, PCE, PCPy, TCP, Hog, Loveboat, Angel Dust	None
Other hallucinogens	I	Bufotenine, Ibogaine, DMT, DET, Psilocybin, Psilocin	None

Controlled Substances — Categorized Listing of the Most Commonly Encountered Controlled Substances (Continued)

Drug	CSA Schedules	Trade or Other Names	Medical Uses
Anabolic Steroids			
Testosterone	III	Depo-testosterone, Delatestryl (Cypionate, Enanthate)	Hypogonadism
Nandrolone	III	Nandrolone, Durabolin, Deca-Durabolin, Deca	Anemia, breast cancer
Oxymetholone	III	Anadrol-50	Anemia

^a Not designated a narcotic under the CSA.

^b Designated a narcotic under the CSA.

1.9.3.2 Listing of Controlled Substances by Schedule Number

Listed below are those substances specifically controlled under the Controlled Substances Act as of June 26, 2006. This list does not include all controlled steroids or controlled substance analogues. These are classes of compounds that are controlled based on chemical and pharmacological criteria that were discussed earlier in this chapter.

Schedule I Controlled Substances

Controlled Substance	Synonym(s)
1-(1-Phenylcyclohexyl)pyrrolidine	PCPy, PHP, rolicyclidine
1-[1-(2-Thienyl)cyclohexyl]piperidine	TCP, tenocyclidine
1-[1-(2-Thienyl)cyclohexyl]pyrrolidine	TCPy
1-Methyl-4-phenyl-4-propionoxypiperidine	MPPP, synthetic heroin
1-(2-Phenylethyl)-4-phenyl-4-acetoxypiperidine	PEPAP, synthetic heroin
2,5-Dimethoxyamphetamine	DMA, 2,5-DMA
2,5-Dimethoxy-4-ethylamphetamine	DOET
2,5-Dimethoxy-4-(n)-propylthiophenethylamine	2C-T-7
3,4,5-Trimethoxyamphetamine	TMA
3,4-Methylenedioxyamphetamine	MDA, Love Drug
3,4-Methylenedioxymethamphetamine	MDMA, Ecstasy, XTC
3,4-Methylenedioxy-N-ethylamphetamine	N-ethyl MDA, MDE, MDEA
3-Methylfentanyl	China White, fentanyl
3-Methylthiofentanyl	China White, fentanyl
4-Bromo-2,5-dimethoxyamphetamine	DOB, 4-bromo-DMA
4-Bromo-2,5-dimethoxyphenethylamine	Nexus, 2-CB, has been sold as Ecstasy, i.e., MDMA
4-Methoxyamphetamine	PMA
4-Methyl-2,5-dimethoxyamphetamine	DOM, STP
4-Methylaminorex (<i>cis</i> isomer)	U4Euh, McN-422
5-Methoxy-3,4-methylenedioxyamphetamine	MMDA
5-Methoxy-N,N-diisopropyltryptamine	5-MeO-DIPT
Acetorphine	
Acetyldihydrocodeine	Acetylcodone
Acetylmetadol	Methadyl acetate
Acetyl-alpha-methylfentanyl	
Allylprodine	
Alphacetylmetadol except levo-alphacetylmetadol	
alpha-Ethyltryptamine	ET, Trip
Alphameprodine	
Alphamethadol	
alpha-Methylfentanyl	China White, fentanyl
alpha-Methylthiofentanyl	China White, fentanyl
alpha-Methyltryptamine	AMT

Schedule I Controlled Substances (Continued)

Controlled Substance	Synonym(s)
Aminorex	Has been sold as methamphetamine
Benzethidine	
Benzylmorphine	
Betacetylmethadol	
Betameprodine	
Betamethadol	China White, fentanyl
Betaprodine	
beta-Hydroxyfentanyl	
beta-Hydroxy-3-methylfentanyl	
Bufotenine	
Cathinone	Mappine, <i>N,N</i> -dimethylserotonin
Clonitazene	Constituent of "Khat" plant
Codeine methylbromide	Palfium, Jetrium, Narcolo
Codeine- <i>N</i> -oxide	
Cyprenorphine	
Desomorphine	
Dextromoramide	
Diampromide	DET
Diethylthiambutene	
Diethyltryptamine	
Difenoxin	Lyspafen
Dihydromorphine	DMT
Dimenoxadol	
Dimepheptanol	
Dimethylthiambutene	
Dimethyltryptamine	
Dioxaphetyl butyrate	Dipipan, phenylpiperone HCL, Diconal, Wellconal
Dipipanone	
Drotebanol	
Ethylmethylthiambutene	
Etonitazene	
Etorphine (except HCL)	Captagon, amfetyline, ethyltheophylline amphetamine
Etoxadine	
Fenethylamine	
Furethidine	
Gamma hydroxybutyric acid	
Heroin	GHB, gamma hydroxybutyrate, sodium oxybate
Hydromorphanol	Diacetylmorphine, diamorphine
Hydroxypethidine	
Ibogaine	
Ketobemidone	
Levomoramide	
Levophenacymorphan	Constituent of "Tabernanthe iboga" plant
Lysergic acid diethylamide	
Marihuana	
Mecloqualone	
Mescaline	
Methaqualone	LSD, lysergide
Methcathinone	Cannabis, marijuana
Methyldesorphine	Nubarene
Methyldihydromorphine	Constituent of "Peyote" cacti
Morpheridine	Quaalude, Parest, Somnafac, Opitamil, Mandrax
Morphine methylbromide	<i>N</i> -Methylcathinone, "cat"
Morphine methylsulfonate	
Morphine- <i>N</i> -oxide	
Myrophine	
<i>N</i> -Benzylpiperazine	
<i>N</i> -Ethyl-1-phenylcyclohexylamine	BZP, 1-benzylpiperazine
	PCE

Schedule I Controlled Substances (Continued)

Controlled Substance	Synonym(s)
<i>N</i> -Ethylamphetamine	NEA
<i>N</i> -Ethyl-3-piperidyl benzilate	JB 323
<i>N</i> -Hydroxy-3,4-methylenedioxyamphetamine	<i>N</i> -hydroxy MDA
<i>N</i> -Methyl-3-piperidyl benzilate	JB 336
<i>N,N</i> -Dimethylamphetamine	
Nicocodeine	
Nicomorphine	Vilan
Noracymethadol	
Norlevorphanol	
Normethadone	Phenylidimazone
Normorphine	
Norpipanone	
Parahehexyl	Synhexyl
para-Fluorofentanyl	China White, fentanyl
Peyote	Cactus that contains mescaline
Phenadoxone	
Phenampromide	
Phenomorphan	
Phenoperidine	Operidine, Lealgin
Pholcodine	Copholco, Adaphol, Codisol, Lantuss, Pholcolin
Piritramide	Piridolan
Proheptazine	
Properidine	
Propiram	Algeril
Psilocybin	Constituent of "Magic Mushrooms"
Psilocyn	Psilocin, constituent of "Magic Mushrooms"
Racemoramide	
Tetrahydrocannabinols	THC, Delta-8 THC, Delta-9 THC, and others
Thebacon	Acetylhydrocodone, Acedicon, Thebacetyl
Thiofentanyl	China White, fentanyl
Tilidine	Tilidate, Valoron, Kitadol, Lak, Tilsa
Trimeperidine	Promedolum

Schedule II Controlled Substances

Controlled Substance	Synonym(s)
1-Phenylethylhexylamine	Precursor of PCP
1-Piperidinoethylhexanecarbonitrile	PCC, precursor of PCP
Alfentanil	Alfenta
Alphaprodine	Nisentil
Amobarbital	Amytal, Tuinal
Amphetamine	Dexedrine, Adderall, Obetrol
Anilerdine	Leritine
Benzoyllecgonine	Cocaine metabolite
Bezitramide	Burgodin
Carfentanil	Wildnil
Coca leaves	
Cocaine	Methyl benzoyllecgonine, Crack
Codeine	Morphine methyl ester, methyl morphine
Dextropropoxyphene, bulk (non-dosage forms)	Propoxyphene
Dihydrocodeine	Didrate, Parzone
Dihydroetorphine	DHE
Diphenoxylate	
Diprenorphine	M50-50
Ecgonine	Cocaine precursor, in coca leaves
Ethylmorphine	Dionin
Etorphine HCL	M 99

Schedule II Controlled Substances (Continued)

Controlled Substance	Synonym(s)
Fentanyl	Duragesic, Oralet, Actiq, Sublimaze, Innovar
Glutethimide	Doriden, Dorimide
Hydrocodone	Dihydrocodeinone
Hydromorphone	Dilaudid, dihydromorphinone
Isomethadone	Isoamidone
Levo-alphaacetylmethadol	LAAM, long-acting methadone, levomethadyl acetate
Levomethorphan	
Levorphanol	Levo-Dromoran
Meperidine	Demerol, Mepergan, pethidine
Meperidine intermediate-A	Meperidine precursor
Meperidine intermediate-B	Meperidine precursor
Meperidine intermediate-C	Meperidine precursor
Metazocine	
Methadone	Dolophine, Methadose, Amidone
Methadone intermediate	Methadone precursor
Methamphetamine	Desoxyn, D-desoxyephedrine, ICE, Crank, Speed
Methylphenidate	Concerta, Ritalin, Methylin
Metopon	
Moramide-intermediate	
Morphine	MS Contin, Roxanol, Oramorph, Duramorph, RMS, MSIR
Nabilone	Cesamet
Opium, granulated	Granulated opium
Opium, powdered	Powdered opium
Opium, raw	Raw opium, gum opium
Opium extracts	
Opium fluid extract	
Opium poppy	Papaver somniferum
Opium tincture	Laudanum
Oxycodone	OxyContin, Percocet, Endocet, Roxicodone, Roxicet
Oxymorphone	Numorphan
Pentobarbital	Nembutal
Phenazocine	Narphen, Prinadol
Phencyclidine	PCP, Sernylan
Phenmetrazine	Preludin
Phenylacetone	P2P, phenyl-2-propanone, benzyl methyl ketone
Piminodine	
Poppy straw	Opium poppy capsules, poppy heads
Poppy straw concentrate	Concentrate of poppy straw, CPS
Racemethorphan	
Racemorphan	Dromoran
Remifentanil	Ultiva
Secobarbital	Seconel, Tuinal
Sufentanil	Sufenta
Thebaine	Precursor of many narcotics

Schedule III Controlled Substances

Controlled Substance	Synonym(s)
1-Androstenediol	
1-Androstenedione	
3 α ,17 β -Dihydroxy-5 α -androstane	
3 β ,17 β -Dihydroxy-5 α -androstane	
4-Androstenediol	4-AD
4-Androstenedione	
4-Dihydrotestosterone	Anabolex, Andractim, Pesomax, Stanolone
4-Hydrotestosterone	

Schedule III Controlled Substances (Continued)

Controlled Substance	Synonym(s)
4-Hydroxy-19-nortestosterone	
5-Androstenediol	
5-Androstenedione	
13 β -Ethyl-7 β -hydroxygon-4-en-3-one	
17 α -Methyl-3 β ,17 β -dihydroxy-5 α -androstane	
17 α -Methyl-3 α ,17 β -dihydroxy-5 α -androstane	
17 α -Methyl-3 α ,17 β -dihydroxyandrost-4-ene	
17 α -Methyl-4-hydroxynandrolone	
17 α -Methyl- Δ^1 -dihydrotestosterone	17 α -Methyl-1-testosterone
19-Nor-4-androstenediol	
19-Nor-5-androstenediol	
19-Nor-4-androstenedione	
19-Nor-5-androstenedione	
Amobarbital suppository dosage form	
Amobarbital and noncontrolled active ingredients	Amobarbital/ephedrine capsules
Anabolic steroids	"Body Building" drugs
Androstenedione	
Aprobarbital	Alurate
Barbituric acid derivative	Barbiturates not specifically listed
Benzphetamine	Didrex, Inapetyl
Boldenone	Equipoise, Parenebol, Vebonol, dehydrotestosterone
Bolasterone	
Buprenorphine	Buprenex, Temgesic, Subutex, Suboxone
Buprenorphine	Buprenex, Temgesic
Butabarbital (sec butabarbital)	Butisol, Butibel
Butalbital	Fiorinal, Butalbital with aspirin
Butobarbital (butethal)	Soneryl (UK)
Calusterone	Methosarb
Chlorhexadol	Mechloral, Mecoral, Medodorm, Chloralodol
Chlorotestosterone (same as clostebol)	If 4-chlorotestosterone then clostebol
Chlorphentermine	Pre-Sate, Lucofen, Apsedon, Desopimom
Clortermine	Voranyl
Clostebol	alpha-Trofodermin, Clostene, 4-chlorotestosterone
Codeine combination product 90 mg/du	Emprin, Fiorinal, Tylenol, ASA or APAP w/codeine
Codeine and isoquinoline alkaloid 90 mg/du	Codeine with papaverine or noscapine
Dehydrochlormethyltestosterone	Oral-Turinabol
Dihydrocodeine combination product 90 mg/du	Synalgos-DC, Compal
Delta1-dihydrotestosterone	1-Testosterone
Dronabinol in sesame oil in soft gelatin capsule	Marinol, synthetic THC in sesame oil/soft gelatin
Dihydrotestosterone (same as stanolone)	See stanolone
Drostanolone	Drolban, Masterid, Permastril
Ethylestrenol	Maxibolin, Orabolin, Durabolin-O, Duraboral
Ethylmorphine combination product 15 mg/du	
Formebolone	Esiclone, Hubernol
Furazabol	Frazalon, Miotolon, Qu Zhi Shu
Gamma Hydroxybutyric Acid preparations	Zyrem
Fluoxymesterone	Anadroid-F, Halotestin, Ora-Testryl
Hydrocodone combination product <15 mg/du	Lorcet, Lortab, Vicodin, Vicoprofen, Tussionex, Norco
Hydrocodone and isoquinoline alkaloid <15 mg/du	Dihydrocodeinone + papaverine or noscapine
Ketamine	Ketaset, Ketalar, Special K, K
Lysergic acid	LSD precursor
Lysergic acid amide	LSD precursor
Mesterolone	Androviron, Proviron, Testiwoop
Mestanolone	Assimil, Ermalone, Methylbol, Tanterone
Methandienone	Dianabol, Metabolina, Nerobol, Perbolin
Methandiol	Sinesex, Stenediol, Troformone

Schedule III Controlled Substances (Continued)

Controlled Substance	Synonym(s)
Methenolone	Primobolan, Primobolan Depot, Primobolan S
Methyldienolone	
Methyltestosterone	Android, Oreton, Testred, Virilon
Methyltrienolone	Metribolone
Methypylon	Noludar
Mibolerone	Cheque, Matenon
Morphine combination product/ 50 mg/100 ml or g	
Nalorphine	Nalline
Nandrolone	Deca-Durabolin, Durabolin, Durabolin-50
Norbolethone	Genabol
Norclostebol	Anabol-4-19, Lentabol
Norethandrolone	Nilavar, Pronabol, Solevar
Opium combination product 25 mg/du	Paregoric, other combination products
Oxandrolone	Anavar, Lonavar, Provitar, Vasorome
Oxymesterone	Anamidol, Balnimax, Oranabol, Oranabol 10
Oxymetholone	Anadrol-50, Adroyd, Anapolon, Anasteron, Pardroyd
Pentobarbital suppository dosage form	WANS
Pentobarbital and noncontrolled active ingredients	FP-3
Phendimetrazine	Plegine, Prelu-2, Bontril, Melfiat, Statobex
Secobarbital suppository dosage form	Various
Secobarbital and noncontrolled active ingredients	Various
Stanozolol	Winstrol, Winstrol-V
Stenbolone	
Stimulant compounds previously excepted	Mediatric
Sulfondiethylmethane	
Sulfonethylmethane	
Sulfonmethane	
Talbutal	Lotusate
Tetrahydrogestrinone	THG
Testolactone	Teolit, Teslac
Testosterone	Android-T, Adrolan, Depotest, Dalatesteryl
Thiamylal	Surital
Thiopental	Pentothal
Tiletamine and zolazepam combination product	Telazol
Trenbolone	Finaplix-S, Finajet, Parabolan
Vinbarbital	Delvinal, Vinbarbitone

Schedule IV Controlled Substances

Controlled Substance	Synonyms
Alprazolam	Xanax
Barbital	Veronal, Plexonal, barbitone
Bromazepam	Lexotan, Lexatin, Lexotanil
Camazepam	Albego, Limpidon, Paxor
Cathine	Constituent of "Khat" plant, (+)-norpseudoephedrine
Chloral betaine	Beta Chlor
Chloral hydrate	Noctac
Chlordiazepoxide	Librium, Libritabs, Lombitrol, SK-Lygen
Clobazam	Urbadan, Urbanyl
Clonazepam	Klonopin, Clonopin
Clorazepate	Tranxene
Clotiazepam	Trecalmo, Rize, Clozan, Veratran
Cloxazolam	Akton, Lubalix, Olcadil, Sepazon
Delorazepam	
Dexfenfluramine	Redux
Dextropropoxyphene dosage forms	Darvon, propoxyphene, Darvocet, Propacet

Schedule IV Controlled Substances (Continued)

Controlled Substance	Synonyms
Diazepam	Valium, Diastat
Dichloralphenazone	Midrin, dichloralantipyrine
Diethylpropion	Tenuate, Tepanil
Difenoxin 1 mg/25 µg AtSO4/du	Motofen
Estazolam	ProSom, Domnamid, Eurodin, Nuctalon
Ethchlorvynol	Placidyl
Ethinamate	Valmid, Valamin
Ethyl loflazepate	
Fencamfamin	Reactivan
Fenfluramine	Pondimin, Ponderal
Fenproporex	Gacilin, Solvolip
Fludiazepam	
Flunitrazepam	Rohypnol, Narcozep, Darkene, Roipnol
Flurazepam	Dalmane
Halazepam	Paxipam
Haloxazolam	
Ketazolam	Anxon, Loftran, Solatran, Contamex
Loprazolam	
Lorazepam	Ativan
Lormetazepam	Noctamid
Mazindol	Sanorex, Mazanor
Mebutamate	Capla
Medazepam	Nobrium
Mefenorex	Anorexic, Amexate, Doracil, Pondinil
Meprobamate	Miltown, Equanil, Deprol, Equagesic, Meprospan
Methohexital	Brevital
Methylphenobarbital (mephobarbital)	Mebaral, mephobarbital
Midazolam	Versed
Modafinil	Provigil
Nimetazepam	Erimin
Nitrazepam	Mogadon
Nordiazepam	Nordazepam, Demadar, Madar
Oxazepam	Serax, Serenid-D
Oxazolam	Serenal, Convertal
Paraldehyde	Paral
Pemoline	Cylert
Pentazocine	Talwin, Talwin NX, Talacen, Talwin Compound
Petrichloral	Pentaerythritol chloral, Periclor
Phenobarbital	Luminal, Donnatal, Bellergal-S
Phentermine	Ionamin, Fastin, Adipex-P, Obe-Nix, Zantryl
Pinazepam	Domar
Pipradrol	Detaril, Stimolag Fortis
Prazepam	Centrax
Quazepam	Doral
Sibutramine	Meridia
SPA	1-Dimethylamino-1,2-diphenylethane, Lefetamine
Temazepam	Restoril
Tetrazepam	Myolastan, Musaril
Triazolam	Halcion
Zaleplon	Sonata
Zopiclone	Lunesta
Zolpidem	Ambien, Ivadal, Stilnoct, Stilnox

Schedule V Controlled Substances

Controlled Substance	Synonyms
Codeine preparations — 200 mg/100 ml or 100 g	Cosanyl, Robitussin A-C, Cheracol, Cerase, Pediacof
Difenoxin preparations — 0.5 mg/25 µg AtSO ₄ /du	Motofen
Dihydrocodeine preparations — 10 mg/200 ml or 100 g	Cophene-S, various others
Diphenoxylate preparations — 2.5 mg/25 µg AtSO ₄	Lomotil, Logen
Ethylmorphine preparations — 100 mg/100 ml or 100 g	
Opium preparations — 100 mg/100 ml or 100 g	Parepectolin, Kapectolin PG, Kaolin, Pectin P.G.
Pregabalin	Lyrica
Pyrovalerone	Centroton, Thymergix

The author gratefully acknowledges the assistance of Dr. Judy Lawrence, Pharmacologist, DEA Office of Diversion Control, for providing information utilized in compiling this listing of controlled substances.

INTRODUCTION

In a very broad sense, the pathology of drug abuse is determined by the particular drug abused, and the way it is used and administered, not to mention its toxic effects and the behavioral modifications it produces. A comprehensive overview of drug abuse pathology would, therefore, include physical injuries from drunk driving and hallucinogenic drugs, a variety of communicable diseases such as viral hepatitis and AIDS acquired from needle sharing, and indirect complications of addiction, such as homicide, prostitution, child abuse and neglect. However, this section is devoted to the pathological changes resulting from the pharmacologic effects of various drugs that are abused, and from the ways that these drugs are administered. In short, we review the changes one would likely encounter at the autopsy table.

A large volume of literature on drug abuse and the pathologic changes it produces has been amassed over the past three or four decades. Much of this material has recently been collected into several excellent comprehensive treatises.^{1,2} Instead of repeating these accomplishments, this chapter focuses on issues of pathology not adequately covered in other references, and concentrates on emerging concepts and newly discovered phenomena. Accordingly, emphasis is placed on death scene investigation, evaluation of the drug abuse victim (living or deceased), and cardiovascular pathology. In many instances, the authors have relied on their own academic and investigative experiences to provide a practical approach to evaluating these victims of drug abuse.

Much of what is known about the pathology of drug abuse has been derived from thorough and carefully performed autopsies. It should therefore be expected that much of this section deals with the autopsy and will be of particular interest to pathologists. However, far from this being an academic exercise, it is hoped that the reader will discern applications to clinical situations. This, in fact, has been accomplished over the years as clinicians have come to better appreciate the pathophysiology of diseases resulting from drug abuse. What is lacking currently, however, is the

proper toxicologic evaluation of the drug abuse victim at the time of admission to a hospital. Except for ethanol, reliance is too often made on a urine drug screen. Blood specimens for toxicologic testing, if obtained at all, are too often quantitatively insufficient or qualitatively inadequate due to lack of proper preservation. Should death occur, for whatever reason, days or weeks later, it is often impossible to adequately evaluate the victim toxicologically. In such cases hair testing may prove to be of some value. In many instances (e.g., delayed deaths from cocaine-induced psychosis) this lack of concrete data leads to deleterious speculation about who may be responsible for the death (e.g., police action or inaction) and this void in knowledge may form the nidus of lawsuits. Conversely, adequate analysis undertaken at the beginning may readily eliminate much needless speculation, and absolve or implicate culpability on the part of others.

Although such evaluations are ideal, the goal is not likely to be met in the immediate future with an environment of cost containment and a medical focus that best describes a patient as a problem of “here and now.” This leaves little consideration for events or questions that may arise in the future regarding adequacy of patient care, or subsequent questions posed by future investigators, including medical examiners, police, and attorneys.³

2.1 THE SCENE OF DEATH AND THE AUTOPSY

Charles V. Wetli, M.D.

Chief Medical Examiner, Office of the Suffolk County Medical Examiner, Hauppauge, New York

Paramount to any investigation, evaluation, or inquiry is the knowledge of terminal events, and pre-terminal characteristics of the victim. In most hospital deaths, the medical record readily provides this. In the world of forensic pathology, such history is often lacking, and reliance must be placed on an open mind with a conscious realization that drug abuse may have had a significant contribution to a person's death regardless of initial impressions: Infectious diseases such as hepatitis or endocarditis may be the result of intravenous drug abuse; cocaine may trigger convulsions or precipitate hypertensive crises and myocardial ischemia; central nervous system (CNS) depressants may lead to positional asphyxia, etc. And there must also be awareness that people with natural disease may, intentionally or not, abuse drugs, which may exacerbate their underlying disease process and significantly contribute to their death. Drugs create pathological states, with or without death, by their immediate pharmacologic effects, the way in which the drug is taken, by the cumulative effects of chronic abuse, and by interaction with pre-existing pathologic conditions.^{1,2} Therefore, what once could have been discussed as a complication of hypertension (e.g., spontaneous aortic dissection) must now be evaluated as a possible effect of acute and chronic cocaine abuse.^{3,4}

As noted in the prologue, every death scene must be approached with a conscious effort to evaluate the role of drugs and alcohol regardless of the apparent cause or manner of death. The scene investigator must therefore be ever cognizant of two possibilities: (1) Because a person has

Figure 2.1.1 Packets of drugs.

a disease it does not necessarily mean it is the cause of death, and (2) the scene of a drug overdose is frequently cleaned before investigators are even called. Consequently, it is important to evaluate all medication containers at the death scene, noting the identity of the drug and its purpose, the instructions for usage, and the number remaining. Such a preliminary inventory (followed later by a more complete inventory and drug confirmation) often leads to a suspicion of drug overdose. However, since others may well have previously tampered with the scene, a search should be made for containers that may be concealed: wastebaskets, beneath the bed, in a purse, etc. All medication and medication containers should be confiscated for a more complete inventory and possible toxicologic evaluation.² Likewise, all drug paraphernalia must be removed from the premises. Recognizing such paraphernalia requires that the investigator be aware of what illicit drugs prevail in a particular community and how they are used. Thus, a small spoon attached to the cap of a small vial, a gold-plated razor with a mirror, and a soda can with holes punched in the sides are all paraphernalia of cocaine abuse. Packets of drugs (often with a crude logo; Figure 2.1.1) and used syringes are particularly important because these items may be the only way to determine the type of drug being abused, its purity, and its excipients. This is especially true for “designer drugs,” which may be many thousand times more potent than heroin and therefore difficult to detect on routine toxicologic analysis of biological specimens.

Besides actual drug containers and paraphernalia, observations should be made that might reflect orientation toward a drug subculture: certain tattoos, evidence of gang affiliation (clothes, hair style, etc.), magazines, posters of drug-oriented music groups, etc. Periodicals and books of right-to-die organizations such as the Hemlock Society and its members should suggest the possibility of suicide or assisted suicide. This literature provides specific instructions about using drugs and plastic bags to commit suicide, and gives suggestions about avoiding (or cooperating) with a medical examiner investigation.^{5,6}

Following scrutiny of the environment, attention should turn to the victim. Of particular importance is to ascertain the exact position of the body when it was found² to establish the possibility of postural or positional asphyxia.⁷ This is a situation where a person collapses in a position such that the airway (nose, mouth) is partially or completely obstructed. Because of the anesthetic effect of the drugs (with or without alcohol), the victim does not move to create an unobstructed airway, and death results from mechanical asphyxia. If the airway obstruction is partial, it may take some hours for death to actually occur from respiratory acidosis and carbon dioxide retention. During this time, the drugs and alcohol continue to be metabolized and eliminated in urine, sweat, or breath. Toxicologic analysis will then reveal a low level of drugs and, if the likelihood of positional asphyxia cannot be established, the cause of death may be a conundrum. At the scene of death it

is important to interview the person who first discovered the body and ask specific questions to ascertain whether the airway could have been obstructed.

Examination of the victim at the scene should include a careful inspection of the hands and mouth for drug residue or pills, palpation for hyperthermia (or, better, a direct measurement with a plastic indicator strip or rectal thermometer), which could suggest death from a stimulant drug; tattoos, which could suggest a drug culture; and fine parallel scars of the wrists or neck suggestive of a prior suicide attempt. A nearby plastic bag, particularly in the death of an elderly person with a chronic disease, suggests a death from the combination of asphyxia and drug overdose to terminate prolonged suffering (a method advocated by right-to-die organizations).

A fairly common mistake of some scene investigators is failure to turn the body over (which may reveal previously hidden drugs or drug paraphernalia) and failure to adequately examine the clothing. Pockets must be turned out or cut open, and underwear searched since they may contain packets or residue of drugs. Two death scenes have sufficient characteristics to suggest specific syndromes of cocaine abuse: cocaine-induced excited delirium, and the cocaine body packer.

2.1.1 Excited Delirium

Excited delirium is a medical emergency with a psychiatric presentation.⁸ The etiology may be infectious or pharmacologic and today it is most often seen with the abuse of cocaine or amphetamines. A similar syndrome of acute exhaustive mania may be seen with psychiatric patients or schizophrenics who have been treated with neuroleptic medication and who have recently stopped taking their medication. Today, the term agitated or excited delirium is used for the same syndrome regardless of etiology (i.e., infectious, toxic, pharmacologic, or psychiatric). Clinical and neuropharmacologic studies have linked the neuroleptic malignant syndrome and drug-induced excited delirium to disturbances of dopamine release and transport in the striatum of the CNS.⁹ The syndrome is characterized by bizarre and violent behavior, hyperthermia, and tremendous, unexpected, strength. It usually takes several people to restrain the victim who is otherwise likely to injure himself or herself or others. Shortly after being restrained, the victim suddenly collapses and dies, often in police custody. If cardiopulmonary resuscitation (CPR) is successful, there is still a potential for death in a few days from myoglobinuric nephrosis secondary to massive rhabdomyolysis.^{10,11} The violence is often associated with extensive property damage, inappropriate disrobing, and varying injuries incurred from smashing glass or the struggle with law enforcement personnel. The injuries may, of themselves, be lethal and hence require careful evaluation and documentation. With cocaine-induced excited delirium, blood and brain concentrations of cocaine are typically quite low whereas concentrations of benzoylecgonine are relatively high.^{12,13} The “typical” scenario is most often that of a male who has been in a violent struggle, who may be naked and with usually minor injuries sustained in a struggle with police. The most common injuries are those involving the ankles or wrists from fighting against handcuffs or hobble restraints. Scalp and neck injuries may also be seen, and require careful evaluation to exclude a traumatic death. Body temperatures of 104°F or more are common, and there is usually evidence of extensive property damage, especially smashed glass.

The exact mechanism of death in excited delirium has yet to be elucidated.^{14,15} The sudden loss of vital signs with asystole or bradycardic pulse-less electrical activity strongly suggests a cardiac mechanism of death, which is also frequently accompanied by an underlying abnormality of the heart (e.g., hypertensive type cardiomegaly) and profound lactic acidosis with a pH of 7.0 or less. Since death often occurs shortly after a violent struggle with the police, there are often allegations that law enforcement tactics generally regarded as a sublethal use of force actually caused or contributed to the death. Most often such allegations allege death resulted from so-called restraint or positional asphyxia, the use of pepper spray or mace, the use of electric stun guns, or the misapplication of a law enforcement neck hold.¹⁶

2.1.2 Body Packers

Body packers are individuals who swallow packets of drugs in one country and transport them to another, and subsequently retrieve the packets by the use of laxatives.¹⁷ Occasionally, larger packets may be inserted in the vagina or rectum. The most popular drug smuggled by this method into the United States in the past two decades has been cocaine. More recently, a number of heroin body packers have been reported.¹⁸ The amount smuggled may total nearly a kilogram of the drug. Death may occur from a pharmacologic overdose if a drug packet breaks or leaks, or if water should cross a semipermeable membrane (e.g., a condom used as a drug packet) and allow the drug to dialyze into the gastrointestinal lumen to be absorbed rapidly into the blood. Intestinal obstruction is another potentially fatal complication. Cocaine body packers may collapse or have fatal grand mal seizures aboard an airplane or in the airport, or may be found dead in a hotel room. Evidence in the hotel room death scene usually consists of passports, foreign currency, or airplane tickets indicating recent arrival from a drug-supplying country (e.g., Colombia), hyperthermia (high body temperature, wet towels, or other evidence suggesting attempts at cooling), seizure activity (usually bite marks of the lower lip or tongue), presence of laxatives or enemas and, sometimes, drug packets hidden in a closet or suitcase. Heroin body packers do not have evidence of hyperthermia or of seizure activity, but often have a massive amount of white frothy pulmonary edema fluid about the nose and mouth. Also, the bodies of heroin body packers are more likely to be dumped alongside a roadway, and accomplices may have attempted to remove the packets via a crude post-mortem laparotomy.¹⁵

Drug packets have been fashioned from balloons, condoms, and other materials. Most commonly, however, the drug is compressed into a cylinder about 1/2 in. in diameter and 1 in. long, wrapped in plastic and heat-sealed, and wrapped again in several layers of latex (e.g., fingers of latex gloves). The ends are tied and sometimes the packet is dipped in wax. The drug packets are visible radiographically, and they may be accentuated by a halo of radiolucency as gas seeps between the layers of wrapping material.¹⁹

2.1.3 The Autopsy

External examination in cases of oral drug abuse (i.e., pills or liquid medications) is generally not rewarding unless actual medication or medication residue is observed in the mouth or on the hands. However, as noted earlier, multiple parallel scars on the wrists or neck suggest prior suicide attempts and a subsequent suicidal drug overdose. Bite marks (contusions and lacerations) of the tongue and lower lip should be specifically sought since these frequently accompany terminal convulsions, which may be the result of cocaine or tricyclic antidepressant toxicity.

The prevalence of cocaine requires careful inspection of the nasal septum (preferably with a nasal speculum) to detect inflammation, necrosis, or perforation (Figure 2.1.2) from the chronic nasal insufflation (snorting) of cocaine hydrochloride. Also, it should be noted that crystals of cocaine might occasionally be observed in the nasal hairs or attached to the bristles of a mustache.

Stigmata of intravenous drug abuse are, naturally, the identification of fresh, recent, and old injection sites (Figure 2.1.3). Sometimes these may not be evident if the user makes a conscious attempt to conceal such marks by using very small gauge needles, rotating injection sites, and by injecting in areas normally concealed even by warm weather clothing. This is especially likely to occur among those in the health professions or in occupations where inspections are frequent (e.g., police, military personnel). These abusers may inject into the ankle or foot, beneath a watchband, in the auxiliary region, or even directly through the abdominal wall and into the peritoneal cavity. If the suspicion is high, "blind" incisions into these areas as well as more likely areas (e.g., antecubital fossae) may reveal extravasated blood in the subcutaneous tissue and around a vein, which is typical for a fresh or recent injection (Figure 2.1.4). Mostly, however, fresh and recent injection sites appear as small subcutaneous ecchymoses surrounding a cutaneous puncture. With

Figure 2.1.2 Inspection of the nasal septum.

cocaine, the needle puncture may be surrounded by a clear halo, which in turn is surrounded by an extensive ecchymoses; recent injection sites appear as poorly demarcated ecchymoses. Intravenous cocaine users may have little or no perivenous scarring even after years of intravenous injections.⁴

Repeated intravenous injections of narcotics generally leave characteristic hyperpigmented or hypopigmented zones of perivenous scarring commonly referred to as “tracks.” These arise because narcotic addicts frequently mix heroin with oral medication containing starch or talc fillers.¹ These act like myriad microscopic splinters to elicit inflammatory (particularly granulomatous) reactions, which eventually form scar tissue. This process, plus venous thrombosis, may eventually occlude the vein. Externally, these tracks appear as irregular subcutaneous “ropes” that follow the veins of the hands and forearms.

Round atrophic scars clustered predominantly on the arms and legs are frequently seen in intravenous drug abusers,⁴ particularly cocaine abusers. These may represent healed abscesses or healed ischemic ulcers due to the vasoconstrictive effect of cocaine (which is also directly toxic to

Figure 2.1.3 Stigmata of intravenous drug abuse are the identification of injection sites.

Figure 2.1.4 “Blind” incision reveals extravasated blood in the subcutaneous tissue and around a vein. This is typical for a fresh or recent injection.

capillary endothelium). More rarely encountered are dramatic instances of necrotizing fasciitis (Figure 2.1.5), which may involve an entire extremity and be accompanied by a severe lymphedema, multiple surrounding ovoid scars, and cellulitis. In extreme cases, auto-amputation of the extremity may occur. The etiology of the fasciitis and the lymphedema is unknown.

Internally, some drugs (e.g., alcohol, ethchlorvynol) may impart a characteristic odor, and some medications contain dyes that may impart a red, green, or blue discoloration to the gastrointestinal tract. *In situ* changes typical of intravenous narcotic abuse include hepatosplenomegaly, enlargement of lymph nodes about the celiac axis and/or porta hepatis, and fecal impaction (from the pharmacologic property of opiates that inhibits intestinal motility).

Toxicologic analysis requires specimens be obtained for drug screening, confirmation, and quantitation as well as tissue distribution and evaluation of drug metabolites. Thus, samples for alcohol determination should be obtained from peripheral blood (e.g., femoral vein), vitreous fluid, and central blood (e.g., aorta or pulmonary trunk); brain alcohol determinations are often useful as well. Urine is ideal for qualitative drug screening. Drugs such as tricyclic antidepressants and

Figure 2.1.5 Necrotizing fasciitis.

propoxyphene are best evaluated by analyzing liver for concentrations of the parent drug and its major metabolites. This is also important for drugs that give spuriously elevated levels in post-mortem blood because of leaching from tissue (tricyclic antidepressants and digitalis are particularly well known to leach from tissues and cause spurious increases in post-mortem blood samples). Other drugs, such as cocaine, not only readily hydrolyze in the post-mortem state but may leach from tissues as well, rendering interpretation of post-mortem drug concentrations in blood even more difficult. For cocaine, brain is the best substance for toxicologic analysis. For routine toxicologic evaluation, samples from the following sites are recommended: peripheral (femoral) blood, blood from aorta and pulmonary trunk, vitreous fluid, bile, liver, brain, and gastric content. In addition, one sample of blood should be centrifuged for post-mortem serum (preserved by freezing) and one preserved with sodium fluoride and refrigerated for long-term storage. Injection sites, the contents of the entire small intestine, hair, and other samples should be obtained as the case dictates.

In recent years, the concept of “post-mortem re-distribution of drugs” has emerged. This is based on the realization that many drugs may have slight or moderate elevations in the post-mortem state, and that the interpretation of post-mortem drug levels does not always correlate with ante-mortem levels. Consequently, popular references now include the post-mortem re-distribution ratio to allow for a more accurate interpretation of post-mortem drug levels.¹⁸

Finally, as a cautionary note, it should be realized that the gastric mucosa is an excretory organ. As such, water-soluble drugs will pass from the blood into gastric juices and therefore be detected in analysis of gastric contents, usually in very low or trace quantities. Therefore, trace amounts of drugs in the gastric content do not imply oral ingestion of the drug. Likewise, very low levels of alcohol in the gastric content do not imply recent ingestion. In evaluating drugs in gastric content, be sure to calculate the absolute amount of the drug present since most laboratories will report out the concentration of the drug, not the total amount present. Thus, 1 mg/L of drug in 50-mL total gastric content calculates to a total drug content of 0.05 mg.

2.2 HEART DISEASE

2.2.1 Techniques for Examination of the Heart*

Renu Virmani, M.D., F.A.C.C.,¹ Allen P. Burke, M.D.,² and Andrew Farb, M.D.³

¹ Medical Director, CVPPath, International Registry of Pathology, Gaithersburg, Maryland

² Kernan Hospital Pathology Laboratory, University of Maryland Medical Center, Baltimore, Maryland

³ U.S. Food and Drug Administration, Rockville, Maryland

The forensic pathologist must examine the heart carefully and methodically in order to obtain maximal information to establish the cause of death. In establishing the manner of death, exclusion of non-cardiac causes is as important as establishing an arrhythmogenic cardiac substrate, because many natural deaths are due to chronic heart diseases that lower the threshold for ventricular

* Reproduced in part and modified from Virmani, R., Ursell, P.C., and Fenoglio, J.J., Jr., Examination of the heart, *Human Pathology*, 18, 432, 1987, and Virmani, R., Ursell, P.C., and Fenoglio, J.J., Jr., Examination of the heart, in *Cardiovascular Pathology*, Virmani, R., Atkinson, J.B., and Fenoglio, J.J., Jr., Eds., W.B. Saunders, Philadelphia, 1991, pp. 1–20.

The opinions or assertions contained herein are the private views of the authors and are not to be construed as official or as reflecting the views of the Department of the Army or Navy or the Department of Defense.

fibrillation, without an acute finding. However, it is becoming more important to pinpoint the cause of natural deaths, for genetic counseling of surviving relatives, for instances of civil litigation, and in occasional deaths where the distinction between natural and accidental death may be difficult.

There is no one “correct” method of examining the heart. In cases of sudden unexpected death in adults, an approach should be utilized that evaluates a large portion of the ventricular myocardium, the site of the vast majority of lethal tachyarrhythmias, and that thoroughly inspects the coronary arteries, the most common site of the cause of ischemic ventricular lesions. In addition, preservation of basic anatomy, in case of further review when the heart can be retained, should be a goal in potentially difficult cases. Last, preservation of frozen tissue or blood in unexplained arrhythmic deaths in young people should be considered.

The preferred method of examination of the heart combines opening of each of the four chambers according to the direction of the flow of blood with bread loafing the myocardium.^{1,2} After inspecting the heart *in situ* for pericardial disease, pericardial fluid, saddle emboli, intraventricular air, and relationships to surrounding structures, the heart is removed. The epicardial surfaces and origins of the great arteries are inspected. The coronary arteries are sectioned serially, and the valves inspected from above. The heart is bread-loafed from the apex to the papillary muscles, without cutting the atrioventricular valves, allowing measurements of ventricular free walls, assessment of ventricular dilatation, and characterization of scars and necrosis, facilitating diagnosis of ischemic heart disease and cardiomyopathies. Then, the base of the heart is opened by direction of flow of blood. Briefly, the right atrium is opened from the inferior vena cava to the tip of the atrial appendage; the right ventricle is opened along its lateral border through the tricuspid valve and annulus to the apex of the right ventricle with extension to the pulmonary outflow tract close to the ventricular septum. The left atrium is opened by cutting across the roof of the atrium between the left and right pulmonary veins, and the left ventricle is opened laterally between the anterior and posterior papillary muscles to the apex and then cut along the anterior wall adjacent to the ventricular septum through the aortic outflow tract.

2.2.1.1 Removal of the Heart

The examination of the adult heart begins after the anterior chest plate has been removed. A longitudinal cut through the anterior aspect of the pericardial sac is made. The amount of pericardial fluid is measured, and its character is noted. The surface of the visceral as well as parietal pericardium is also examined for exudates, adhesions, tumor nodules, or other lesions. A short longitudinal incision 2 cm above the pulmonary valve will enable a check for thromboemboli in the main pulmonary trunk *in situ*. The heart is removed by cutting the inferior vena cava just above the diaphragm and lifting the heart by the apex, reflecting it anteriorly and cephalad to facilitate exposure of the pulmonary veins at their pericardial reflection. After it is confirmed that the pulmonary veins enter normally into the left atrium, the pulmonary veins are cut. The aorta and the pulmonary trunk, the last remaining connections, are cut transversely 2 cm above the semilunar valves. Following removal of the heart from the pericardial cavity and before weighing the specimen, post-mortem blood clots should be removed manually and gently by flushing the heart with water from the left and right atria.

2.2.1.2 Examination of Coronary Arteries

For research in coronary atherosclerosis, the ideal method of examining the coronary arterial tree requires injecting the coronary arteries with a barium-gelatin mixture and studying the vessels in radiographs.^{3,4} Alternatively, in cases of suspected coronary artery disease, the heart may be perfusion fixed with 10% buffered formaldehyde retrograde from the ascending aorta at 100 mm Hg pressure (Figure 2.2.1) for at least 1 h. In the absence of perfusion fixation, which is impractical for routine forensic evaluation, careful dissection of fresh or immersion-fixed coronary arteries is

Figure 2.2.1 Diagram showing the method used for perfusion fixation of the heart. The constant head chamber is placed 135 cm above the perfusion chamber, and is connected via polyethylene tubing to the ascending aorta through the Lucite plug. The excess formaldehyde is suctioned back into the constant head chamber via a pump. Both chambers are covered in order to reduce formalin vapors. (Courtesy J. Frederick Cornhill, D. Phil.)

acceptable, provided that it is understood that precise assessment of percent stenosis is not possible, and that all segments are sectioned adequately in decalcified arteries if necessary.

For perfusion fixation, a specially constructed Lucite plug or a rubber stopper with central tubing is inserted into the aorta, taking care that the Lucite/rubber plug does not touch the aortic valve. The Lucite plug is attached to tubing that is connected to the perfusion chamber.⁵ The latter is placed 135 cm above the specimen, and this provides gravity perfusion pressure that is equivalent to 100 mm Hg. As a result, the coronary arteries are fixed in a distended state that approximates the dimensions observed in living patients. Myocardial fixation is also affected, but cardiac chambers are not fixed in a distended state.

This method is fairly simple, does not require sophisticated equipment to achieve good fixation, and allows for immediate dissection after perfusion for approximately 30 min. If perfusion fixation is impractical, the heart should be fixed for 24 h in 10% formaldehyde (10 parts of formaldehyde to 1 part of specimen) before cutting. Radiography of the heart is recommended to determine the extent of coronary and valvular calcification but is not essential; if coronary arteries are heavily calcified, they need to be decalcified prior to cutting at 3- to 4-mm intervals.

The vessels that must be examined in all hearts include the four major epicardial coronary arteries: the left main, the left anterior descending, the left circumflex, and the right coronary arteries. However, it is not unusual to see severe luminal narrowing in smaller branches of the main coronary arteries; left diagonals, left obtuse marginal, ramus (intermediate) branch, and the posterior descending coronary arteries (Figure 2.2.2).

Figure 2.2.2 Diagram of the right and left epicardial coronary arteries as they arise from the aorta. The four major arteries that must be described in detail are right (RCA), left main (LM), left anterior descending coronary (LAD), and the left circumflex (LC) coronary arteries. Not uncommonly severe coronary (>75% cross-sectional area luminal narrowing) artery disease may affect the smaller branches (IB = intermediate or also called ramus branch, LD = left diagonal, LOM= left obtuse marginal, PDA = posterior descending artery, and RMB = right marginal branch).

Following fixation and/or decalcification, the coronary arteries are cut transversely at 3- to 4-mm intervals with a sharp scalpel blade by a gentle sawing motion (not by firm pressure) to confirm sites of narrowing and to evaluate the pathologic process (e.g., atherosclerotic plaques, thrombi, dissections) directly. If the coronary arteries are heavily calcified, it is desirable to remove the coronary arteries intact. Following dissection of the vessel from the epicardial surface, each coronary artery is carefully trimmed of excess fat and the intact arterial tree is placed in a container of formic acid for slow decalcification over 12 to 18 h.

Decalcification of isolated segments of vessel may be sufficient for cases in which the coronary arteries are only focally calcified. The areas of maximal narrowing are noted by specifying the degrees of reduction of the cross-sectional area of the lumen (e.g., 0 to 25%, 26 to 50%, 51 to 75%, 76 to 90%, 91 to 99%, and 100%). Most cardiologists agree that, in the absence of other cardiac disease, significant or severe coronary artery narrowing is that exceeding a 75% cross-sectional luminal narrowing. Particular attention should be paid to the left main coronary artery because disease in this vessel is very important clinically but frequently overlooked at autopsy.⁶

Cross sections from areas of maximal narrowing from each of the four major epicardial coronary arteries or their branches are selected for histological examination. Sections of all coronary arteries containing thrombi are taken to aid in determining the type of underlying plaque morphology, i.e., plaque rupture, or plaque erosion (ulceration). The site of maximal narrowing must be specified, i.e., proximal, middle, or distal coronary involvement. This is of great medicolegal importance in cases where the patient may have been inadequately examined in the physician's office or emergency room or in the hospital following chest pain. It is the location of the severe narrowing that determines if the patient is operable or not; presence of distal disease signifies non-operability.

2.2.1.3 Examination of Coronary Interventions

Coronary interventions consist primarily of open bypass surgery and percutaneous coronary interventions (PCI). The technique for evaluation of bypass grafts is tailored to the circumstances of death. In cases of perioperative death, or when there is question of graft patency, careful dissection is necessary. In cases where it is not possible to perfusion-fix the heart, the heart may be immersion fixed in 10% buffered formaldehyde overnight. Prior to cutting the arteries and the grafts, it is

Figure 2.2.3 Radiograph of epicardial coronary arteries and saphenous vein bypass graft (arrows) to left circumflex (LC) removed at autopsy. Note focal calcification of the native arteries and absence of calcification of the vein graft. A portion of the left anterior coronary artery is surrounded by myocardium (bridged or tunneled coronary artery). Arteries are decalcified prior to sectioning and embedding in paraffin. (From Virmani, R., Ursell, P.C., and Fenoglio, J.J., Examination of the heart, in Virmani, R., Atkinson, J.B., and Fenoglio, J.J., Eds., *Cardiovascular Pathology*, W.B. Saunders, Philadelphia, 1991, pp. 1–20. With permission.)

useful to radiograph and decalcify them when necessary (Figure 2.2.3). The important features to document are the numbers of the grafts, patency of aortic anastomoses, sites of distal anastomoses, and patency of run-off arteries. It is helpful to remember that grafts that were never patent or closed soon after surgery have a cord-like appearance, without open lumen; that all types of anastomoses are possible, including Y-grafts, touch-down (end-to-end) anastomoses, and interpositions of radial arteries; and that characteristics of native artery at the distal anastomoses (presence of plaque, size of vessel) influence long-term patency.

After inspecting the aortic origin of vein grafts, the grafts themselves are inspected for lumen patency, fibrous intimal thickening, atherosclerotic plaques with or without calcification, and aneurysms. Twists, as well as excessive tautness between aorta and distal anastomosis, are noted.⁷ Anastomotic sites are sectioned in different ways depending on whether the connection is end to end or end to side (Figure 2.2.4). When reporting the findings in the heart, it is important to mention each graft separately; including the location of the aortic orifice, whether it is involved by atherosclerotic ulcerated lesion or not, and if present mention if atheroemboli could have embolized and may be the source of the infarct noted in the heart. Describe the course of the graft and the native coronary vessel to which it is distally anastomosed. Give the size of the native vessel, i.e., less than or greater than 1 mm diameter; vessels less than 1 mm in diameter usually do not carry enough blood to meet the demands of the myocardium. Also, determine if there is severe distal disease present in the grafted vessel.

If the cause of death is related to surgery, the full extent of the saphenous vein grafts is best visualized by barium–gelatin mixture followed by radiography. It is best to inject all the vein grafts simultaneously and to obtain radiographs before injection of the coronary arteries. This enables more detailed study of the native coronary arteries distal to the graft as well as at the coronary

Figure 2.2.4 Diagram illustrating coronary artery bypass grafts that have end-to-side and side-to-side anastomoses in two separate grafts (shaded area) to left anterior descending and right coronary arteries, respectively. The figure illustrates the method used for sectioning of anastomotic site with end-to-side and side-to-side anastomoses to demonstrate if any of the three mechanisms for obstruction in the anastomotic site are present (i.e., compression or loss of arterial lumen, which may occur if the majority of the arterial wall has been used for anastomosis; thrombosis at the site of anastomosis; and dissection of the native coronary-artery at the site of anastomosis) and if the coronary artery has severe narrowing at the site of anastomosis due to severe atherosclerotic change. (Modified from Bulkley, B.H. and Hutchins, G.M., Pathology of coronary artery bypass graft surgery, *Arch. Pathol.*, 102:273, 1978. From Virmani, R., Ursell, P.C., and Fenoglio, J.J., Examination of the heart, in Virmani, R., Atkinson, J.B., and Fenoglio, J.J., Eds., *Cardiovascular Pathology*, W.B. Saunders, Philadelphia, 1991, pp. 1–20. With permission.)

graft anastomosis. Measurements of lumen diameters may be made from the radiographs. In those cases in which the internal mammary artery is anastomosed to the coronary system, the internal mammary artery is injected from where it has been severed during removal of the heart. The native coronary arteries are injected, fixed, and radiographed to evaluate the extent of disease in the remainder of the coronary arterial tree. If, as mentioned previously, it is not feasible to inject the heart with a barium–gelatin mixture, then the heart may be perfusion fixed with formaldehyde from the aortic stump taking care that the graft orifices are below the Lucite plug and the internal mammary artery should be ligated near the site of severance from the chest wall.

The grafts and native arteries may then be removed from the heart, radiographed, and cut at 3- to 4-mm intervals to determine the extent of luminal narrowing, the presence or absence of thrombi, and/or the extent of atherosclerosis in vein grafts and coronary arteries.^{8–11}

The forensic pathologist is encountering intracoronary stents at an ever-increasing pace. As is the case with bypass grafts, the degree of evaluation depends on the circumstances of death. Incidentally found stents are commonly encountered in patients with a history of ischemic heart disease by post-mortem radiography. If a death occurs soon after PCI, the heart should be radiographed, site(s) of stenting established, and the stented segments fixed in formalin. The only method for

determining in-stent thrombosis involves plastic embedding and sectioning or stent removal without damaging the lumen contents. Either of these procedures requires consultation with a laboratory specializing in such techniques. Immediate fixation of the stented segments and mailing them in adequate formalin to the consultant will provide for documentation of adequacy of stent placement, characterization of underlying plaque, therapeutic misadventures, and in-stent thrombosis.

2.2.1.4 Examination of the Myocardium in Ischemic Heart Disease

In the presence or absence of acute or healed myocardial infarction, the myocardium is best examined by slicing the ventricles in a manner similar to a loaf of bread. To evaluate the specimen, a series of short-axis cuts are made through the ventricles from apex to base (Figure 2.2.5A). This method is best accomplished using a long, sharp knife on the intact fixed specimen following examination of the coronary arteries. With the anterior aspect of the heart downward (against the cutting board), the cuts are made parallel to the posterior atrioventricular sulcus at 1- to 1.5-cm intervals from the apex of the heart to a point approximately 2 cm caudal to the sulcus or up to the mid-portion of the papillary muscles of the left ventricle.

The result is a series of cross sections through the ventricles, including papillary muscles with the atrioventricular valve apparatus left intact in the remainder of the specimen. The location and extent of the infarct is noted. Locations may be stated using terms relating to the standard anatomic terms of reference (e.g., anteroseptal, posterolateral). The extent of infarction may be described in terms of circumference of the ventricle involved¹²⁻¹⁴ and longitudinal portion of the ventricle involved (e.g., basal third, middle third, apical third; Figure 2.2.5A and B).

The distribution within the wall is also described (e.g., transmural or subendocardial; transmural when the infarct extends from the endocardium to the epicardium, and subendocardial when <50% of the left ventricular wall is infarcted). The gross pathologic appearance of the myocardium serves as a relatively good index as to the age of the infarct but must be confirmed by histologic examination. Even if infarction cannot be identified grossly, it is important to section the myocardium in the distribution of the severely diseased coronary arteries more extensively.

2.2.1.5 Examination of the Heart in Cardiomyopathy

The short-axis sectioning (bread-loafing) method described above serves well for the examination of the cardiomyopathic heart. Cardiac hypertrophy and dilation may be demonstrated quite effectively by this method. If the left ventricular cavity measures >4 cm, excluding the papillary muscles, it is considered that the patient was in congestive heart failure prior to death even if there is no history to corroborate the autopsy findings. Left ventricular hypertrophy is said to be present if the left ventricular wall measures >1.5 cm. On the other hand, if the left ventricular wall measures <1.5 cm but the heart weight is increased and the left ventricular cavity is enlarged, then there will be microscopic appreciation of myocyte hypertrophy.

Histological examination of the myocardium is critical to determining the cause of the cardiomyopathy. Thus, in addition to sections of tissue with obvious gross pathology, samples of the walls of all four cardiac chambers, the septum, and papillary muscles should be taken. In the past, the right ventricle has been relatively ignored, but because of the greater awareness of right ventricular infarction and right ventricular dysplasia/cardiomyopathy, it should be a routine to examine the right ventricle carefully. For establishing the diagnosis of right ventricular cardiomyopathy, the most helpful single observation to make is one of fibrosis or scarring in the right ventricular wall with intermingling of fat; these lesions are most often seen in the inflow region of the right ventricle on the posterior wall or in the anterior wall of the right ventricular outflow tract. These lesions can be commonly appreciated grossly if a careful examination of the heart is carried out.

Figure 2.2.5 The location and extent of myocardial infarction must be indicated by the size, that is, how much of the base to apex is infarcted: basal one third, and/or middle one third, and/or apical one third or more than one third from base to apex. The diagram in (A) shows a long-axis view of the heart with regional nomenclature. (B) The location of the myocardial infarction in the left ventricle must also indicate the wall in which the infarction occurred: anterior, posterior, lateral, septal, or any combination of these. This diagram illustrates a short-axis view through the basal, middle, and apical portions of the right and left ventricles. (Ao = aorta; Ant = anterior; ALPM = anterolateral papillary muscle; AML = anterior mitral leaflet; Inf = inferior; LA = left atrium; LV = left ventricle; Mid = middle; PML = posterior mitral leaflet; PMPM = posteromedial papillary muscle; Post = posterior; RV = right ventricle; VS = ventricular septum) (Modified from Edwards, W.D., Tajik, A.J., and Seward, J.B., Standardized nomenclature and anatomic basis for regional tomographic analysis of the heart, *Mayo Clin. Proc.*, 56:479, 1981. From Virmani, R., Ursell, P.C., and Fenoglio, J.J., Examination of the heart, in Virmani, R., Atkinson, J.B., and Fenoglio, J.J., Eds., *Cardiovascular Pathology*, W.B. Saunders, Philadelphia, 1991, pp. 1–20. With permission.

The heart also may be cut in four-chamber view by cutting the heart from the apex to base, along the acute margin of the right ventricle and the obtuse margin of the left ventricle and continuing the plane of section through the atria (Figure 2.2.6). This four-chamber view is best for evaluating the atrial and ventricular chamber size. In cases of hypertrophic cardiomyopathy, the heart should be cut in the long axis view of the left ventricular outflow tract. The plane of dissection of the aortic valve leaflet is through the right coronary and the posterior non-coronary leaflets, the anterior and the posterior mitral leaflets, the posterior and the anterior left atrial wall, ventricular septum, posterolateral wall of the left ventricle and the anterior right ventricular wall (Figure 2.2.7). Sections to determine the presence of fibromuscular disarray are taken in the transverse plane, usually from the septal location with the largest dimension.

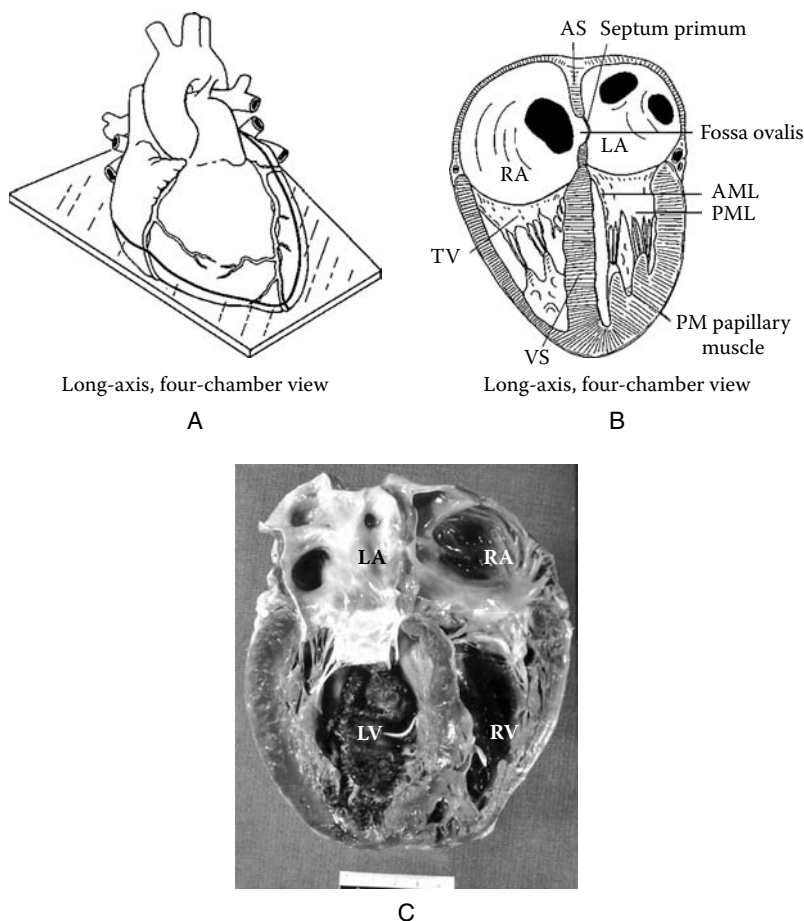

Figure 2.2.6 (A) Diagram of the heart demonstrating the ultrasonic tomographic plane used for obtaining the long-axis view of the heart. This four-chamber view is best used for evaluating the atrial and ventricular dimensions, intracavitary masses, ventricular and atrial septal defects, atrioventricular valve abnormalities, ventricular aneurysms, and the drainage of pulmonary veins. (B) Diagram demonstrating the four-chamber view of the heart. This method involves sectioning the heart from apex to base, along the acute margin of the right ventricle and the obtuse margin of the left ventricle and continuing the plane of sectioning through the atria. The bisected specimen that is photographed should match the ante-mortem cardiac image. (C) Tomographic analysis of a heart from a 17-year-old boy who developed progressive heart failure over the course of 8 months, showing four-chamber view with biventricular hypertrophy, four-chamber dilatation, and apical right and left ventricular thrombus. (RA = right atrium; LA = left atrium; VS = ventricular septum; TV = tricuspid valve; AML = anterior mitral leaflet; PML = posterior mitral leaflet) (Modified from Tajik, A.L., Seward, I., Hager, D.J., Muir, D.D., and Lie, J.T., Two-dimensional real-time ultrasonic imaging of the heart and great vessels: Technique, image orientation, structure identification and validation, *Mayo Clin. Proc.*, 53:271, 1978. From Virmani, R., Ursell, P.C., and Fenoglio, J.J., Examination of the heart, in Virmani, R., Atkinson, J.B., and Fenoglio, J.J., Eds., *Cardiovascular Pathology*, W.B. Saunders, Philadelphia, 1991, pp. 1–20. With permission.)

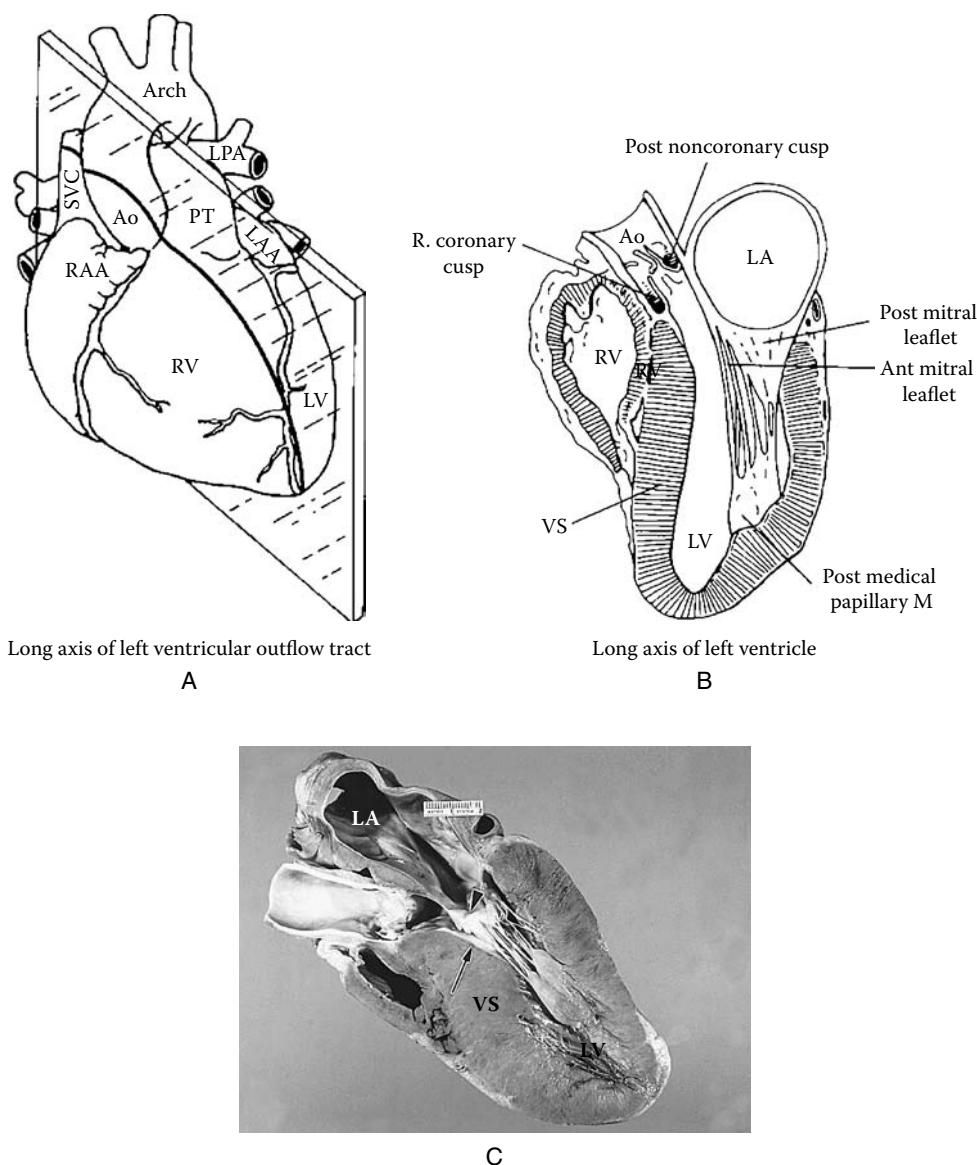

Figure 2.2.7 (A) Diagram of the heart demonstrating the ultrasonic plane of the long-axis view of the left ventricular outflow tract. The normal anatomic relationship of septal-aortic and mitral-aortic continuity is best shown by this plane of dissection. This method is used for aortic root pathology, including valvular, supra-ventricular, and intravalvular obstructions, left ventricular chamber size, posterior wall abnormalities, ventricular septal defects, mitral valve disease, and left atrial size. (B) Anatomic landmarks seen with a long-axis view of the left ventricle. The plane of dissection of aortic valve leaflets is through the right coronary and posterior non-coronary leaflets. (C) Left ventricular long-axis section in hypertrophic cardiomyopathy, showing asymmetric septal hypertrophy with a discrete left ventricular outflow tract plaque (arrow) and a thickened anterior mitral leaflet (arrow head). (Ao = aorta; LA = left atrium; LPA = left pulmonary artery; LV = left ventricle; RAA = right atrial appendage; RV = right ventricle; SVC = superior vena cava; VS = ventricular septum) (Modified from Tajik, A.J., Seward, J.B., Hager, D.J., Muir, D.D., and Lie, J.T., Two-dimensional real-time ultrasonic imaging of the heart and great vessels: Technique, image orientation, structure identification and validation, *Mayo Clin. Proc.*, 53:271, 1978. From Virmani, R., Ursell, P.C., and Fenoglio, J.J., Examination of the heart, in Virmani, R., Atkinson, J.B., and Fenoglio, J.J., Eds., *Cardiovascular Pathology*, W.B. Saunders, Philadelphia, 1991, pp. 1–20. With permission.)

2.2.1.6 Examination of the Heart Valves

In the case of valvular heart disease, the valves are best studied intact. The atrial and ventricular aspect of the atrioventricular valves and the ventricular and arterial aspects of the semilunar valves are examined (Figure 2.2.8). Thus, the tricuspid valve is exposed by a lateral incision through the right atrium from the superior vena cava to 2 cm above the valve annulus. Similarly, the mitral valve may be studied following opening of the left atrium via an incision extending from one of the left pulmonary veins to one of the right pulmonary veins and another incision continuing through the atrium laterally to a point 2 cm above the annulus. If a valve abnormality requires closer inspection, the atria, including the interatrial septum, may be removed 1 to 2 cm above the atrioventricular valves (Figure 2.2.8A). The ventricular aspects of the atrioventricular valves may be viewed following removal of the serial slices of ventricle as described previously.

The semilunar valves are best studied after removal of the aorta (Figure 2.2.8C) and the main pulmonary artery at a point just above the coronary ostia or valve annulus. In selected cases, the valvular pathology may be best visualized using a four-chamber cut¹⁵⁻¹⁷ in the plane including both

Figure 2.2.8 (A) The appearance of the atrioventricular valves after removal of both the atria. The mitral valve has been replaced with a bioprosthetic porcine valve, which shows a tear in the muscular leaflet close to the ring. (B) The right atrium has been removed close to the tricuspid valve. Note the valve margins are thickened and the commissure between the posterior and the septal leaflet is fused secondary to chronic rheumatic valvulitis. (C) The aortic valve is examined on removal of the aorta close to sinotubular junction. There is diffuse thickening of the valve, which is more marked at the free margins with one of the three commissures fused (arrow). These changes are consistent with chronic rheumatic valvulitis. (AV = aortic valve; MV = mitral valve; PV = pulmonary valve; TV = tricuspid valve). (From Virmani, R., Ursell, P.C., and Fenoglio, J.J., Examination of the heart, in Virmani, R., Atkinson, J.B., and Fenoglio, J.J., Eds., *Cardiovascular Pathology*, W.B. Saunders, Philadelphia, 1991, pp. 1-20. With permission.)

the acute and obtuse margins of the heart (Figure 2.2.6). The aortic valve may be demonstrated by a left ventricular long-axis cut passing from the apex through the outflow tract, ventricular septum, anterior mitral valve leaflet, and aortic valve (Figure 2.2.7). Measurement of the circumference of annuli, especially in valvular stenosis, is on the whole not very useful. In ectasia of the aorta, it is indeed a must to measure the aortic annulus as the valve will be normal in appearance but the annulus will be dilated. Examination of the heart valves should document the type and severity of the valvular disease and its effect on the cardiac chambers and this includes microscopic evaluation.

In cases in which histology of a valve may be helpful, the leaflets are sectioned together with a portion of the adjacent chambers and/or vessel walls. For example, the posterior leaflet of the mitral valve is sectioned including a portion of the left atrium and left ventricular free wall, while the anterior leaflet includes ventricular septum and non-coronary cusp of the aortic valve. In cases of rheumatic heart disease, sections of the atrial appendages are submitted for histological examination because the incidence of Aschoff's nodules is highest in these structures.

2.2.1.7 Prosthetic Heart Valves

The objectives for examinations of valve implants include determination of (1) the type of implant (bioprosthesis or mechanical valve) and its size and position regarding annulus and chamber; (2) adequacy of movement of the valve apparatus; (3) presence of thrombi, vegetations, and paravalvular abscesses or leaks; and (4) evidence of valve degeneration.¹⁵ In particular, paravalvular abscesses may not be visible without careful inspection of the native annulus following removal of the implant. Demonstration of any pathology may be enhanced using short-axis cuts through the atrioventricular junction.

2.2.1.8 Examination of the Aorta

Because atherosclerosis is the most common lesion affecting the aorta, the aorta should be opened longitudinally along its posterior or dorsal aspect from the ascending aorta through the bifurcation and into both common iliac arteries. The extent of disease and the types of lesions may then be described. While this method enables inspection of the complete intimal surface, it may not be optimal for certain types of pathology, such as aortic aneurysms, which may best be demonstrated by cross-sectional slices 1 to 1.5 cm apart in the perfusion-fixed, distended specimen (Figure 2.2.9). Aortic dissections may be examined by a longitudinal cut (long-axis cut) with the aorta cut into anterior and posterior halves (Figure 2.2.10) or by transverse cut at 1- to 1.5-cm intervals after the aorta has been allowed to fix for 24 h in a distended state or free floating in anatomic position in formaldehyde.

2.2.1.9 Examination of the Heart in Apparent Cardiac Death without Morphologic Abnormality

In a significant proportion of apparent arrhythmic deaths, in which toxicologic and scene investigation do not result in a non-natural cause, the gross and histological examination of the heart is normal. In the past, it was assumed that histological examination of the specialized conduction system held the key to finding a possible abnormality to explain death. In the last decades, however, it has become clearer that a large proportion of sudden deaths with normal hearts are due to genetic defects in the cardiac ion channels. It must always be kept in mind that the origin of arrhythmias is generally in the working myocardium. Nevertheless, examination of the conduction system is still worthwhile, in that it allows evaluation of areas at the base of the heart, including small vessels, which may be prone to arterial dysplasia, or small vessel disease, which has been implicated in sudden death.

Figure 2.2.9 (A) External view of the abdominal aorta with an infrarenal aneurysm (arrows). Note the size, which is best expressed as the largest diameter. In this case, it is 7 cm. (B) Same aneurysm cut transversely at 1.0 to 1.5 cm apart. Note the extent of luminal (L) narrowing secondary to an organizing thrombus. (From Virmani, R., Ursell, P.C., and Fenoglio, J.J., *Examination of the heart*, in Virmani, R., Atkinson, J.B., and Fenoglio, J.J., Eds., *Cardiovascular Pathology*, W.B. Saunders, Philadelphia, 1991, pp. 1–20. With permission.)

With practice and careful attention to anatomic landmarks, the conduction system is relatively easily sampled histologically.^{18,19} In most humans, the sinus node is a spindle-shaped structure located in the sulcus terminalis on the lateral aspect of the superior vena cava and the right atrium (Figure 2.2.11). In some patients, it is a horseshoe-shaped structure wrapped across the superior aspect of this cavoatrial junction. Histologically, the sinus node consists of relatively small diameter, haphazardly oriented atrial muscle cells admixed with connective tissue, collagen, and elastic fibers (Figure 2.2.12). Often, the artery to the sinus node can be identified in or around the nodal tissue. Because the sinus node is not visible grossly, the entire block of tissue from the suspected area should be taken and serially sectioned, either in the plane perpendicular to the sulcus terminalis (parallel to the long axis of the superior vena cava) or in the plane containing the sulcus (perpendicular to the vessel). In small infants, serial sectioning of the entire cavoatrial junction is preferred.

There are no anatomically distinct muscle tracts for conduction through the atria. The impulse is collected in the atrioventricular node, which is located within the triangle of Koch in the floor of the right atrium. In the heart dissected in the traditional manner along the lines of blood flow, this region is delineated by the following landmarks: the tricuspid valve annulus inferiorly, the coronary sinus posteriorly, and the continuation of the valve guarding the coronary sinus (tendon of Todaro) superiorly (Figure 2.2.11). The atrioventricular node lies within Koch's triangle (Figure 2.2.11), and the apex of the triangle anteriorly denotes the point at which the common bundle of His penetrates the fibrous annulus to reach the left ventricle. After penetrating the fibrous annulus at the crest of the ventricular septum, the bundle of His divides into left and right bundle branches.

Thus, the tissue excised for study of the conduction system must include this area completely. From the opened right atrioventricular aspect (with the aortic outflow tract adjacent to the cutting surface) the block to be excised reaches from the anterior margin of the coronary sinus to the

Figure 2.2.10 The heart has been cut in the long-axis plane, exposing the right and left ventricles and the aortic root and valve. In this plane, the anterior wall of the aorta has been removed. Note the dissecting aneurysm that starts just distal to the subclavian artery and extends along the greater curvature of the aorta to just below the left renal artery (arrowhead). Within the false lumen there are fibrous strands (arrows) connecting the outer media and adventitia to the inner media and intima. Note also the organizing thrombus within a fusiform aneurysm distal to the subclavian and within the abdominal aorta of the false lumen. (From Virmani, R., Ursell, P.C., and Fenoglio, J.J., Examination of the heart, in Virmani, R., Atkinson, J.B., and Fenoglio, J.J., Eds., *Cardiovascular Pathology*, W.B. Saunders, Philadelphia, 1991, pp. 1–20. With permission.)

Figure 2.2.11 Diagram of location of the atrioventricular (AV) and sinoatrial (SA) nodes along with the landmarks that help in locating their positions during sectioning of the heart. (Modified from Davies, M.J., Anderson, R.H., and Becker, A.E., *The Conduction System of the Heart*, Butterworth & Co, London, 1983. From Virmani, R., Ursell, P.C., and Fenoglio, J.J., Examination of the heart, in Virmani, R., Atkinson, J.B., and Fenoglio, J.J., Eds., *Cardiovascular Pathology*, W.B. Saunders, Philadelphia, 1991, pp. 1–20. With permission.)

Figure 2.2.12 (A) The sinus node (outlined) lies in the subepicardium. The superficial layer is surrounded by epicardial fat (F), and the deeper layers anastomose with the surrounding atrial myocardium (MYO). (Movat stain, $\times 25$.) (From Virmani, R., Ursell, P.C., and Fenoglio, J.J., Examination of the heart, in Virmani, R., Atkinson, J.B., and Fenoglio, J.J., Eds., *Cardiovascular Pathology*, W.B. Saunders, Philadelphia, 1991, pp. 1–20. With permission.) (B) High-power view of the SA node showing fibrous tissue, elastin fibers, and small SA node haphazardly arranged fibers.

medial papillary muscle of the right ventricle, including 1 cm of atrium and ventricle on both sides of the valve. Alternatively, from the left ventricle outflow tract, the block can be cut perpendicular to the aortic valve from the margin of attachment of the anterior leaflet of the mitral valve to the left edge of the membranous septum.

The block should include the non-coronary cusp of the aortic valve and the crest of the ventricular septum (Figure 2.2.13). In either case, the block of tissue removed should be divided in the plane perpendicular to the annulus, from posterior to anterior; the block to be sectioned should be marked with India ink so its orientation can be maintained throughout the embedding process. The atrioventricular node, bundle, and bundle branches are histologically easily identifiable. The atrioventricular node consists of a network of muscle fibers that are smaller than the atrial and ventricular fibers. The cytoplasm is pale in comparison with the ventricular myocardium, but striations and intercalated disk are present. The nuclei are oval in longitudinal sections. The conduction tissue is markedly cellular due to the presence of a large number of endothelial cells and there is a greater amount of elastic tissue than in the surrounding myocardium. As the node extends to penetrate the fibrous body and become bundle of His, the fibers are less plexiform and more longitudinally oriented (Figure 2.2.14).

Genetic analysis of mutations that may be the cause of sudden cardiac death in morphologically normal hearts is a complex undertaking. The numerous syndromes associated with sudden death without structural heart disease were originally described by clinical features (e.g., long QT syndrome, Brugada syndrome, polymorphous ventricular tachycardia). As the genetic bases for these lesions have been discovered, terminology has slowly shifted to the genes or proteins involved, including sodium and potassium channels (LQT genes/Brugada syndrome), calcium channel–related genes (ryanodine receptor/RyR2), ankyrin-B, etc. From a diagnostic standpoint, some of these mutations are more likely to cause sudden death during exertion, some more specifically with drowning, and others at rest. From this starting point, the hundreds of possible mutations may potentially be screened, in the dozens of exons in each target gene. Archiving frozen tissue is critical in maintaining the possibility of a genetic diagnosis, as enhanced techniques allowing for simultaneous screening of multiple genes becomes possible. At the time of this writing, the genetic diagnosis of sudden death due to cardiac ion channel disease, in the absence of a family history, is difficult and time-consuming, and nearly impossible with archived paraffin-embedded tissue, which greatly limits the size of DNA segments that can be sequenced.

(From Virmani, R., Ursell, P.C., and Fenoglio, J.J., Examination of the heart, in Virmani, R., Atkinson, J.B., and Fenoglio, J.J., Eds., *Cardiovascular Pathology*, W.B. Saunders, Philadelphia, 1991, pp. 1–20. With permission.)

Figure 2.2.14 (A) The atrioventricular node (arrows) is shown nested against the fibrous annulus (FA). (From Virmani, R., Ursell, P.C., and Fenoglio, J.J., Examination of the heart, in Virmani, R., Atkinson, J.B., and Fenoglio, J.J., Eds., *Cardiovascular Pathology*, W.B. Saunders, Philadelphia, 1991, pp. 1–20. With permission.) (B) The bundle of His branching portion. Note the location underneath the fibrous body (FB) and above the septal myocardium (MYO). (Movat stain, $\times 25$.)

2.2.1.10 Evaluating Cardiac Hypertrophy

One of the most important decisions while examining the heart is to determine if the heart is normal or abnormal. The heart may not show any anatomic structural abnormality except that it is hypertrophied. Because cardiac hypertrophy may be a cause of death if severe, and physiologic in cases of chronic conditioning, the criteria for increased heart weight are important. We usually utilize the tables published from the Mayo Clinic giving the 95% confidence intervals for the height and weight of male and female individuals from birth to 99 years.^{20,21} We recommend that at least four sections of the left ventricle be examined from the four walls of the heart and one section of

the posterior wall of the right ventricle; sections should be taken from the mid-ventricular slice. In elderly individuals we also like to take one section each from both the atria, as amyloidosis and drug reactions may be limited to the atria.

2.2.1.11 Conclusions

This brief description of the examination of the heart is no substitute for the practice of examination and cutting open the heart oneself. In practice, not all methods may be applicable in each laboratory, for each individual, or in all situations. The description is geared more to the forensic pathologist and the examination of the adult heart with intent of making the method easy yet thorough; a careful examination of the heart is worth the time and effort.

Statistics provided by the Drug Abuse Warning Network (DAWN) over the past two decades have documented an increasing prevalence in substance abuse as manifested by emergency room and Medical Examiner data (i.e., drug mentions). For example, the Office of the Chief Medical Examiner (OCME) has reported a marked increase in the number of drug abuse deaths in Maryland from 1986 to 1993, with drug deaths increasing sharply from 119 cases in 1986 to 356 in 1993, a 199% increase over seven years.¹ Narcotic drugs, specifically heroin, have played a major role in the rising number of drug abuse deaths.¹ Not surprisingly, cardiovascular complications have accompanied this increase. However, characterizing the effects of drugs of abuse on the vasculature is difficult because not all abused drugs result in anatomic changes. Direct human studies are scarcely available, and the studies that exist are performed under limited, controlled conditions which do not replicate the usage picture or conditions of the drug abuser. The drugs may have multiple effects depending on the dose, route of administration, impurities, underlying risk factors for cardiovascular disease, and concomitant use of other drugs such as ethanol and caffeine. In this section, the underlying pathogenic mechanisms associated with substance abuse leading to vascular complications (Table 2.2.1) is discussed.

Vasoconstriction at the epicardial or microvascular level may result in ischemia of almost any organ, but the vessel often fails to show any morphologic change. Drugs may also lead to formation of intravascular thrombi resulting in organ infarcts. A common complication of drug abuse may be cutaneous or cerebral manifestations of vasculitis. In some instances, acute hemodynamic worsening of hypertension may also lead to dissection of the aorta and rupture of arterial aneurysms resulting in intracranial hemorrhage.

There are several morphologic manifestations of drug-induced vascular disease. Vasoconstriction in itself is rarely identifiable by histologic methods, although contraction band necrosis of smooth muscle cells has rarely been reported in cases of clinically documented vasoconstriction. Chronic vasoconstriction may result in medial hypertrophy. Luminal thrombosis may be secondary to endothelial damage, underlying atherosclerosis, or effects of drugs on the clotting cascade. Atherosclerosis, which is a complex process involving lipid metabolism, endothelial dysfunction, immune activation, and thrombosis may be accelerated in persons exposed to drugs (Figure 2.2.15).

Figure 2.2.15 Cocaine-induced coronary atherosclerosis. The right (A) and the left anterior descending (LAD, B) coronary arteries are severely narrowed by atherosclerotic plaque. The LAD (B) shows a superficial luminal thrombus (plaque erosion) consisting of fibrin and few inflammatory cells. The left circumflex (D,E,F) shows organized thrombus totally occluding the lumen. In (D), the recanalized channel is occluded by a thrombus (arrow). (G) Epicardial small branches of coronary arteries show severe intimal proliferation probably secondary to an organizing thrombus. The patient, a 30-year-old male, was a known cocaine abuser.

Fibrointimal proliferation (increased numbers of intimal smooth muscle cells either via migration from the media or intimal proliferation) may be secondary to toxic endothelial damage. Inflammatory vascular diseases (vasculitis) have been described as a drug-related effect. The two major types of drug-induced vasculitis occur either via antigen-antibody complex deposition, usually in arterioles and venules (small vessel or hypersensitivity vasculitis, Figure 2.2.16), or via direct toxic damage (toxic vasculitis, Figure 2.2.17), generally involving muscular arteries. Both types of vasculitis are characterized by fibrinoid necrosis of vascular walls, especially toxic vasculitis with occlusion by luminal thrombosis and/or fibrointimal proliferation and vessel rupture.

Figure 2.2.16 Small cell (hypersensitivity) vasculitis. There is a predominantly lymphoid infiltrate surrounding an arteriole, with focal neutrophilic karyorrhexis within the arterial wall. The patient had a cutaneous rash (palpable purpura) following exposure to diazepam, to which she was sensitized.

Figure 2.2.17 Toxic arteritis (polyarteritis). There is segmental destruction of the media with aneurysm formation. Residual intact media is present (arrowheads). The patient was a 24-year-old amphetamine addict who expired from mesenteric arteritis and peritoneal hemorrhage.

2.2.2.1 Cocaine

Of all the known drugs of abuse associated with vascular toxicity, cocaine abuse is the most common. The recent increase in cocaine abuse has predominantly occurred due to the availability of cocaine base, known on the streets as crack, which produces an instant euphoria when smoked. The mechanisms of cocaine-induced vascular toxicity are complex. Acute administration of cocaine (whether in the base or hydrochloride form) causes an increase in heart rate and blood pressure. Myocardial oxygen consumption increases from systemic catecholamine release and increased alpha-adrenergic effects due to a blockade of norepinephrine reuptake.²⁻⁴ Cocaine also acts as a local anesthetic by inhibiting sodium influx into cells, and this is most likely responsible for the vasodilatory action of the drug. The anesthetic effects of cocaine are expected at higher doses while the sympathomimetic actions are more likely to be prevalent at lower concentrations. Cocaine is detected in the circulation immediately after its consumption with a plasma half-life of approximately 1 h. However, the half-life for euphoria is less than 1 h which may lead to the repetitive use of cocaine.

The blood cocaine levels required to produce the euphoric effects is approximately 10^{-7} to 10^{-5} mol/L; median plasma levels following intravenous cocaine use in cocaine related deaths is reported to be approximately 6×10^{-7} mol/L to 3×10^{-4} mol/L.⁵⁻⁷ “Binge users” of cocaine are known to use high doses for extended periods, oftentimes up to 200 h.⁸ Plasma concentrations during a “binge” have not been documented although it is thought that the effects of cocaine on the cardiovascular system are especially significant during bingeing. Following absorption, cocaine is cleared from the circulation, primarily hydrolyzed to benzoylecgonine and metabolized to ecgonine methyl ester (by plasma cholinesterases). At least in cerebral vessels, cocaine metabolites appear to be biologically active and may partially contribute to cocaine’s toxic effects.⁹ Furthermore, because of individual variability in plasma cholinesterase activity, cocaine abusers with low enzyme levels may be predisposed to the cardiotoxic effects of the drug. In humans, cocaine is rapidly metabolized, and less than 1% is excreted in urine; the major fraction of an administered dose of cocaine is recovered in urine predominantly as ecgonine methyl ester and benzoylecgonine.^{10,11}

Vasospasticity and Microvascular Resistance

Coronary spasm has been repeatedly proposed as a mechanism of the unexplained sudden cardiac death in young cocaine abusers.¹² Clinical studies with intranasal cocaine administration in patients

undergoing coronary arteriography for the evaluation of chest pain have demonstrated a moderate reduction in luminal caliber and microvascular resistance.¹³ Although cocaine-induced vasospasm has not been demonstrated clinically, ergonovine-induced coronary spasm has been reported to occur at the site of severe coronary lesions in young cocaine abusers.¹⁴ Animal experiments have confirmed that cocaine results in only a minimal diffuse diminution in coronary artery caliber.¹⁵ Such non-critical reduction in luminal diameter is presumably clinically insignificant. It therefore seems likely that acceleration of atherosclerotic lesions must form a substrate for the hypersensitive vasoconstrictive response of a vessel to cocaine consumption. In support of this, cocaine-induced vasoconstriction has been shown to be enhanced at sites of significant fixed stenosis.¹⁶

Alternatively, coronary vasospasm in cocaine abusers may be associated with an increase in adventitial mast cells. A significantly higher prevalence of adventitial mast cells in victims of cocaine-associated sudden cardiac death have been reported when compared to individuals without a history of substance abuse.¹⁷ Similarly, increased adventitial mast cells have been demonstrated at autopsy in patients who had clinically documented vasospastic angina in the absence of severe atherosclerotic coronary disease.¹⁸ Mast cells are a rich source of histamine, which is often used as a provocative test to induce spasm in patients with suspected variant angina.^{19,20} Furthermore, other mast cell products such as prostaglandin D2 and leukotrienes C4 and D4 are also modulators of vascular smooth muscle tone; prostaglandin D2-induced vasoconstriction is 5- to 10-fold more potent than norepinephrine.²¹

Thrombosis

Multiple studies have reported angiographic evidence of coronary thrombosis in young cocaine abusers, predominantly associated with minor atherosclerotic irregularities of coronary arteries. On the other hand, the autopsy data from the young patients with cocaine abuse-associated acute coronary thrombosis leading to sudden cardiac death have demonstrated that approximately 40% of patients suffer from severe atherosclerotic lesions of one or more major coronary arteries.^{22,23} The average age of the cocaine abusers in these reports was approximately 30 years. However, the decreased prevalence of angiographically determined atherosclerotic disease in cocaine abusers may result from angiographic underestimation of the atherosclerotic lesions due to the relatively diffuse nature of the disease.²⁴⁻²⁶ The thrombi isolated from these autopsy examinations have been demonstrated to be rich in platelets^{17,22,23} and are characteristically not associated with rupture of the underlying plaques (Figure 2.2.18).

The mechanism of cocaine-induced thrombosis is not clear. Reports of the direct effects of cocaine on platelet function *in vitro* have been inconclusive and contradictory: cocaine either stimulates or inhibits aggregation.²⁷⁻³¹ However, it is thought that cocaine-induced platelet activation may occur *in vivo* due to indirect effects of the drug. Evidence in support of this hypothesis comes from studies in which platelet activation assessed *ex vivo* by P-selectin expression was increased in long-term habitual cocaine abusers and in dogs treated with cocaine.^{32,33} Alternatively, coronary spasm may also explain the increased prevalence of thrombosis associated with cocaine abuse.

Accelerated Atherosclerosis

Recent post-mortem studies in patients have emphasized that accelerated atherosclerosis may be an important etiologic factor in cocaine-induced acute coronary syndromes.^{17,22-24} Kolodgie et al.³⁵ conducted a retrospective analysis of aortic sudanophilic lesions in asymptomatic young (median age, 25 years) cocaine abusers. After controlling for known risk factors of atherosclerosis, cocaine abuse was the only significant predictor of the extent of sudanophilia, suggesting that cocaine abuse was an independent risk factor for lipid infiltration in the vessel wall.³⁵ Accelerated atherosclerosis attributed to cocaine has been demonstrated experimentally in hypercholesterolemia-induced atherosclerosis in rabbits.³⁶ Also, cocaine abusers with coronary thrombosis have an

Figure 2.2.18 Cocaine-induced coronary thrombosis. (A) There is moderate (50%) luminal narrowing by atherosclerotic plaque composed of fibrointimal thickening consisting of smooth muscle cells in a proteoglycan-collagen matrix. (B) A higher magnification demonstrating a platelet thrombus overlying a plaque rich in smooth muscle cells and proteoglycans (plaque erosion).

increase in inflammatory cell infiltrate in severely narrowed atherosclerotic coronary arteries (Figure 2.2.15). Various mechanisms such as cocaine-related increase in plasma lipids, direct and indirect increase in endothelial permeability, higher prevalence of mast cells and other inflammatory cells in plaques may contribute to the lesions as discussed below.

Endothelial Dysfunction

As described above, atherosclerotic lesions occur prematurely and are likely to be more severe in cocaine abusers. Furthermore, these lesions develop regardless of the presence of conventional risk factors. Cocaine-induced endothelial cell dysfunction may be one of the predisposing factors, but whether this involves a direct and/or indirect action of the drug is unknown. Cocaine has been shown to disrupt the balance of endothelial prostacyclin and thromboxane production, which may be related to the increased tendency toward thrombosis and vasospasm observed in some cocaine abusers.^{37,38} *In vitro* cell culture studies have demonstrated that cocaine increases the permeability function of endothelial cell monolayers as a possible mechanism of accelerated atherosclerosis.³⁶ Cocaine-treated endothelial cell monolayers demonstrated an increased permeability to horseradish peroxidase without affecting cell viability. Furthermore, cocaine-induced release of intracellular calcium stores may result in dysregulation of cytoskeletal integrity.³⁹ It has also been suggested that cocaine may suppress endothelial cell growth,³⁹ cause focal loss of endothelial cell integrity, or produce areas of extensive endothelial cell sloughing.^{40,41}

As discussed earlier, the sympathomimetic effects of cocaine are associated with a transient but marked increase in blood pressure and some degree of vasoconstriction. These transient hemodynamic aberrations may cause endothelial injury. Indeed, cholesterol-fed rabbits typically develop atherosclerotic lesions in the thoracic aorta at sites of increased endothelial cell turnover.

Cocaine-related endothelial dysfunction may be associated with impairment of endothelium-dependent vasorelaxation. Forearm blood flow during acetylcholine infusion in long-term cocaine abusers was significantly lower when compared with subjects without a prior history of drug abuse.⁴² Whether attenuation of endothelial-dependent vasodilatory mechanisms by cocaine results from lethal injury to the endothelium, insensitivity of smooth muscle cells to nitric oxide, or inhibition of enzymatic pathways responsible for nitric oxide synthesis remains to be determined.

Hemodynamic Alterations

Hypertension related vascular complications have been commonly reported with sympathomimetic drugs such as cocaine. Sympathomimetic actions secondary to acute or chronic cocaine abuse are well documented and may result from peripheral inhibition of neuronal reuptake of monoamines and increased epinephrine release from the adrenal medulla as well as central activation of the sympathetic nervous system. The transient increase in blood pressure, at least after acute cocaine abuse, has been associated with aortic dissection (Figure 2.2.19), rupture of aortic aneurysms, and hemorrhagic strokes in patients with preexisting hypertension.⁴³⁻⁴⁵ Recently, intracranial hemorrhage has also been shown to be associated with cocaine abuse.⁴⁶⁻⁴⁹ Of the 17 non-traumatic cases of intracranial hemorrhage analyzed at autopsy, 10 were associated with cocaine: 7 cases had intracerebral hemorrhage while 3 had ruptured berry aneurysms.⁴⁹ No pathologic evidence of vasculopathy was present in these patients.

Figure 2.2.19 Cocaine-induced aortic dissection. (A) Multiple cross-sections through the aorta from the ascending aorta to the descending thoracic segment demonstrate dissection beginning at the aortic arch. (B) A cross-section through the descending thoracic aorta demonstrates the rupture site (arrow) of the false lumen. This rupture resulted in hemothorax and the death of the patient, who was a 24-year-old habitual cocaine abuser. (C) The dissection plane within the media (M) is clearly evident in this cross-section that demonstrates the intimal tear. (D) The true (T) and false (F) lumens can be distinguished readily in this cross-section demonstrating the medial flap.

Vasculitis

Cocaine-vasculitis has rarely been observed. Occasional cases of hypersensitivity vasculitis, similar to development of an Arthus reaction in experimental animals,⁵⁰⁻⁵⁶ have been observed. Vasculitis characteristically results in fibrinoid necrosis of arteriolar and venular walls associated with disintegrating polymorphonuclear cells and histochemical localization of immunoglobulins and complement.^{57,58} The lesions may eventually evolve into loose granulomas consisting of palisading lymphocytes admixed with eosinophils and macrophages and, seldom, giant cells.^{57,58} The most common site of vascular involvement in humans is skin; kidneys are involved in one half and liver in a third.⁵⁸

Cocaine is also reported to induce systemic necrotizing arteritis of predominantly medium and small-sized cerebral arterial vessels frequently at branch points.^{54,59} Affected areas characteristically have marked necrotic lesions with neutrophilic infiltration and various stages of healing. No giant cells or granulomas are seen, and the vascular adventitia is not involved. The mechanism of drug-induced necrotizing vasculitis has not been established and could be either immunological or directly toxic.

Synergy with Other Drugs

It is estimated that half the individuals consume alcohol during cocaine bingeing, and this promotes hepatic transformation of cocaine to cocaethylene.⁶⁰⁻⁶⁷ Cocaethylene has a substantially longer half-life and therefore its persistent systemic presence may increase the likelihood of cocaine cardiotoxicity. Cocaethylene has more potent sodium channel blocking activity compared to cocaine and its proarrhythmic effects may also be related to sudden death in the setting of ischemic myocardium.⁶⁹

Another common drug that may be abused with cocaine is morphine. Morphine is a known secretagogue of mast cells that have been shown to be present in strikingly higher numbers in cocaine-associated atherosclerotic lesions. Mast cells are believed to play an important role in cocaine-related vasospastic manifestations.⁷⁰

Similarly, synergistic interactions have been demonstrated for cocaine and cigarette smoking. Both agents are known to increase the metabolic demands on the heart but may also reduce oxygen supply. Moliteno et al.⁷¹ have reported the influence of intranasal cocaine and cigarette smoking, alone and together, on myocardial oxygen demand and coronary artery dimensions in 42 subjects with and without atherosclerosis. Although none of the patients developed chest pain or ischemic electrocardiographic changes after cocaine use or cigarette smoking, oxygen demand increased by approximately 10% after either cigarette smoking or cocaine use, and by 50% after their simultaneous consumption. While the diameter of the normal coronary artery decreased by 6 to 7% with the use of either or both substances, reduction in the luminal diameter of the diseased artery segments for cigarette smoking, cocaine use, and both substances was 5%, 10%, and 20%, respectively.

2.2.2.2 Methamphetamine

The vascular effects of amphetamines have considerable similarity with sympathomimetic amines (ephedrine, phenylpropanolamine) and cocaine, which is alike structurally. Methamphetamine is abused orally, intravenously, or smoked in a crystal form ("ice"). Methamphetamine is metabolized to amphetamine, independent of the route of administration. Acute toxicity to amphetamine may manifest as rhabdomyolysis, disseminated intravascular coagulation, pulmonary edema, vascular spasm, and acute myocardial infarction. The ring substituted amphetamines 3,4-methylenedioxymethyl-amphetamine (MDMA, "ecstasy") and 3,4-methylenedioxyethylamphetamine (MDEA, "eve") have emerged as popular recreational drugs of abuse over the last decade.⁷² Pharmacological studies indicate that these substances produce a mixture of central stimulant and

psychedelic effects, many of which appear to be mediated by brain monoamines, particularly serotonin and dopamine.⁷³

Chronic use of amphetamines may result in systemic and coronary artery vasospasm that results in an increased cardiac workload, impaired myocardial blood supply, and congestive failure, similar to end-stage hypertension. Sudden cardiac death may also occur. A few reports describe acute myocardial infarction associated with amphetamine abuse.⁷⁴ Potential explanations include coronary vasospasm, excessive catecholamine discharge resulting in ischemic myocardial necrosis, and catecholamine-mediated platelet aggregation with subsequent thrombus formation. The syndrome closely resembles acute myocardial infarction by cocaine abuse. As with cocaine toxicity, a deleterious effect of associated treatment with beta-blockers in the setting of myocardial infarction has also been observed.^{71,75} Acute renal failure due to accelerated hypertension following the ingestion of 3,4-methylenedioxymethamphetamine (“ecstasy”) has been reported.⁷⁶

A necrotizing vasculitis resembling polyarteritis nodosa (Figure 2.2.17) has been reported in young abusers of methamphetamine, which may affect cerebral or visceral arteries. Histologically, there is fibrinoid necrosis of the media and intima of muscular arteries, with a neutrophilic eosinophilic, lymphocytic, and histiocytic infiltrate. Lesions at various stages may be seen with fresh thrombi in early lesions, florid intimal proliferation with marked luminal narrowing in subacute lesions, and destruction of the elastic lamina with replacement by collagen and luminal obliteration in later lesions. The cerebral effects of amphetamines are similar to those of other sympathomimetic amines (ephedrine and phenylpropanolamine).

Heroin

Heroin (diacetylmorphine) is a synthetic morphine derivative which, after administration, is hydrolytically deacetylated to 6-acetyl-morphine and excreted in the urine. Heroin has been associated with cerebral arteritis⁷⁷ and visceral polyarteritis.⁷⁸ Heroin may also have a direct toxic effect on the terminal hepatic veins,⁷⁹ the acute lesion being described as an inflammatory infiltrate of neutrophils and mononuclear cells in sinusoidal lumina and terminal veins, which progresses to fibrosis of the central veins. Heroin is also associated with glomerular injury which may result in malignant hypertension. This heroin-associated nephropathy seen in African-American intravenous drug addicts has given way in the 1990s to HIV-associated nephropathy as a result of shared needles.⁸⁰

Nicotine

Nicotine is well known to simulate the release of catecholamines, resulting in vasoconstriction and other vascular effects of catecholamine release.^{81,82} In addition, there may be direct toxicity of nicotine to vascular endothelial cells *in vitro*,⁸³ and an inhibition of apoptosis, which may contribute to an increase in smooth muscle cells within atherosclerotic plaques, possibly by monoclonal proliferation.⁸⁴ Nicotine has been found to be chemotactic for human neutrophils but not monocytes,⁸⁵ and in contrast to most other chemoattractants for neutrophils, does affect degranulation or superoxide production. Thus, nicotine may promote inflammation which may indirectly contribute to some of the associated vasculopathies. Nicotine transdermal patches used to help nicotine addiction have been associated with a leucocytoclastic vasculitis.^{86,87}

Solvents (“Glue Sniffing”)

Inhalation abuse of volatile solvents, previously known generically as “glue sniffing,” is typically pursued by adolescents.⁸⁸ Glue sniffing has been associated with myocardial infarction, presumably secondary to coronary spasm as no fixed coronary lesions were identified by angiography.⁸⁹ The

mechanism of sudden death in solvent sniffers is believed to be related to enhanced cardiac sensitivity to endogenous catecholamines.⁹⁰

Vasculopathies Associated with Legitimate Medications

The sympathomimetic effects of tricyclic antidepressants are well documented, and overdose with these tricyclic amines is a major source of morbidity and mortality.⁹¹ The most common cardiovascular effect of tricyclic amines is orthostatic hypotension, which is particularly serious in the elderly because it may lead to falls resulting in serious physical injuries. Severe orthostatic hypotension is more likely to develop in depressed patients with left ventricular impairment and/or in patients taking other drugs such as diuretics or vasodilators.⁹² With chronic therapeutic administration, tricyclic antidepressants and phenothiazines have been associated with myocardial ischemia and infarction in the absence of fixed coronary lesions.⁹³

Ergot Alkaloids — The ergot alkaloids are characterized by a nucleus of lysergic acid with the addition of side chains which divide the group into amino acids and amine alkaloids. Ergotamine, an example of an amino acid alkaloid, and methysergide, an example of an amine alkaloid, are both currently used in the prophylaxis and treatment of migraine headaches. The sclerotium of the fungus *Claviceps purpurea* is especially rich in ergot alkaloid, and was responsible for outbreaks of epidemic ergotism (St. Anthony's fire) following the mass ingestion of improperly stored rye in wet seasons. Ergot alkaloids have been used in large doses as an abortifacient.⁹⁴

The toxic effects of ergot alkaloids include acute poisoning resulting in vasospasm and gangrene (usually as a complication of the induction of abortion), and acute idiosyncratic vasospasm secondary to a small dose of the drug. In this country, by far the most common form of ergot alkaloid toxicity is secondary to chronic ingestion of ergotamine, although outbreaks of St. Anthony's fire are still occasionally documented in developing countries.^{94,95} Of recent incidence, bromocriptine mesylate, when used for the suppression of lactation in the puerperium, has been reported to cause generalized or focal vasospasm affecting the cardiac and/or cerebral blood vessels.⁹⁵

The most common clinical manifestations of ergot alkaloid vasospasm are upper and lower extremity ischemia, which may result in claudication and ischemic ulcers of gangrene.⁹⁶ Other vasospastic sequelae of methylsergide or ergotamine toxicity include transient ischemic attacks, stroke (Figure 2.2.20), cardiac angina, and intestinal angina. Angiographic studies reveal narrowed

Figure 2.2.20 Ergotomine-induced fibrointimal proliferation. The carotid artery demonstrates marked narrowing by minimally cellular fibrointimal proliferation. The patient was a 45-year-old woman with chronic ergotamine toxicity who expired from a cerebrovascular accident. Elastic van Gieson stain.

vessels, which may show gradual smooth narrowing or irregular outlines with focal stenosis.^{96,97} Laboratory studies are generally normal. A history will reveal chronic ingestion of ergotamine or methysergide, usually for migraine headaches, often by self-medication or doses exceeding the therapeutic recommendations. Symptoms often remit following cessation or lowering of medication dosage.

Pathologically, there are few vascular changes in acute cases of ergot poisoning, although contraction bands and medial necrosis may be noted within arterial walls. Chronic forms of ergotamine toxicity may have normal histologic findings⁹⁸ or changes consistent with chronic vasoconstriction, including medial hypertrophy, intimal proliferation, intimal hyalinization, and luminal thrombosis.

The mechanism(s) of ergot alkaloid toxicity are not yet completely clear. Physiologic doses result in vasoconstriction of painfully dilated cranial arteries, generally by the interaction of ergot with alpha-adrenergic receptors (alpha-adrenergic blockade) and serotonin antagonism.⁹⁹ Toxic vasoconstriction may occur secondarily to a direct effect of ergot on the arterial media, exacerbated by a direct toxic effect on the capillary endothelium. High levels of platelet-derived growth factor have been detected in an individual with chronic ergotism, suggesting that growth factors are released as a result of chronic endothelial damage.⁹⁸

Ephedrine and Pseudoephedrine

Ephedrine and pseudoephedrine are sympathomimetic amines that may cause hypertension and tachyarrhythmias due to beta-adrenergic stimulation. Toxic effects may result from overdose, drug interactions (e.g., serotonin reuptake inhibitors), or diseases that increase sensitivity to sympathomimetic agents.¹⁰⁰ Reported adverse events range in severity from tremor and headache to death and include reports of stroke, myocardial infarction, chest pain, seizures, insomnia, nausea and vomiting, fatigue, and dizziness.^{101,102} Ephedrine is the preferred vasoconstrictor for the treatment of hypotension after epidural and spinal anesthesia in obstetrics because it preserves uterine perfusion better than pure alpha-adrenergic agonists. Although during pregnancy the vasoconstrictor response to ephedrine is diminished, its stimulatory effect on nitric oxide synthase may release nitric oxide.¹⁰³

The incidence of patients developing cerebral hemorrhage, presumably by the development of toxic vasculitis, is rare.¹⁰⁴ Reported cases of cerebral hemorrhage secondary to ephedrine are fewer than those complicating the use of phenylpropanolamine and amphetamines.¹⁰⁴⁻¹⁰⁷ Clinical management of ephedrine overdose is mostly supportive and requires establishing respiration, initiating emesis, administering activated charcoal and a cathartic, and monitoring the patient's blood pressure, ECG, fluid intake, and urinary output.¹⁰⁸

Phenylpropanolamine

Phenylpropanolamine is a synthetic sympathomimetic amine that is found in cold medications and diet pills. Although the vascular effects of phenylpropanolamine were previously considered minor, relative to ephedrine and amphetamine, increasing reports of toxicity in patients taking larger doses of this drug, especially in diet pills, have led to a reappraisal of the potential toxicity of the drug.

Cerebral hemorrhage has been reported in phenylpropanolamine toxicity after a dose of 50 mg or more.¹⁰⁶ In some commonly used anorexiant, including methamphetamine and phenylpropanolamine, an association with stroke has been reported.^{108,109} Angiography in individuals with phenylpropanolamine toxicity has demonstrated vascular beading that has been ascribed to both vasospasm and to vasculitis.^{106,110} In occasional instances in which histologic examination was performed, a necrotizing vasculitis has been identified.^{105,106} It is unknown what proportions of

phenylpropanolamine-, amphetamine-, and ephedrine-induced cerebral hemorrhages are due to vasculitis, and what proportions are due to vasospasm related to catecholamine release.¹⁰⁶

L-Tryptophan

The eosinophilia-myalgia syndrome associated with the ingestion of L-tryptophan was first recognized in late 1989.¹¹¹ Similar pathologic manifestations of eosinophilic myalgia syndrome share many features with the toxic oil syndrome caused by ingestion of adulterated rapeseed oil in Spain.¹¹² Although available over the counter in the U.S., L-tryptophan is dispensed only by prescription in Germany. Epidemiologic studies strongly suggest that the offending toxin is a contaminant used in the preparation of tryptophan, and not tryptophan itself.¹¹³ Putative offending agents from suspected lots of L-tryptophan include 1,1'-ethylidenebis(tryptophan) and 3-phenylamino-1,2-propanediol, an aniline derivative. Most symptomatic patients are those that chronically ingest large doses of tryptophan (500 mg to several grams a day), although a dose-related toxic effect was not observed in an epidemiological study of German patients.¹¹¹ Vascular effects include pulmonary hypertension resulting from obstruction of pulmonary vessels.¹¹² Intermittent coronary spasm resulting in episodes of myocardial damage has also been reported.¹¹⁵ Fibrointimal proliferation of small coronary arteries has also been described in patients with eosinophilia myalgia syndrome associated with L-tryptophan.¹¹⁶

Because L-tryptophan is metabolized to a number of compounds, including kynurenine, quinoate, serotonin, 5-hydroxyindoleacetic acid, and homovanillic acid, a potential vasospastic role of one or more of these compounds has been investigated. A recent study did not find a link between any of these compounds and coronary vasospasm, but implicated increased levels of eosinophil granule major basic protein.¹¹⁵

2.3 MYOCARDIAL ALTERATIONS IN DRUG ABUSERS

Steven B. Karch, M.D., FFFLM

Consultant Pathologist and Toxicologist, Berkeley, California

Specific diseases of the myocardium of drug abusers are rarely reported, and the true incidence of myocardial disease in this group remains unknown. The absence of myocardial disease among drug abusers is probably more apparent than real. Many pathologists still do not recognize modest degrees of hypertrophy as representing disease. Another confounder preventing accurate estimation of myocardial disease in drug abusers is that observed frequency of any particular myocardial lesion depends upon the population being studied, and the drugs that they use. Patterns of drug abuse have changed a great deal over the last decade. It is likely that the type of lesions encountered has changed as well.

Prior to the advent of the cocaine and HIV pandemics, when heroin was the main drug of abuse, the incidence of myocardial disease among drug users was apparently the same as in controls. In Siegel and Helpert's classic paper on the "Diagnosis of Death from Intravenous Narcotism," heart disease was never even mentioned,¹ nor were any significant cardiac abnormalities recorded in Wetli's study of 100 consecutively autopsied drug abusers.² When Louria analyzed the discharge diagnosis of addicts admitted to Bellevue Hospital's general medical service, 40 years ago, he found that the incidence of endocarditis was less than 10%; no other types of heart disease were mentioned.³

The advent of HIV, coupled with the rise in cocaine and methamphetamine abuse, has drastically changed the landscape. So has the unarguable fact that we now live (or soon will live) in the age of the molecular autopsy; hearts that look normal at autopsy, and which even appear normal under the microscope may, in fact, be diseased (channelopathies and other heritable disorders). At the same time, it has also become very clear that the extracellular matrix, the tissue surrounding myocytes, is not just inert scaffolding but, rather, an active, hormone-secreting tissue, exerting potent effects on myocardial structure (the process of myocardial remodeling).

2.3.1 Epidemiology

Whether or not damage occurs to the myocardium depends both on the drug and the way it is administered. In areas where the injection of pills meant for oral use is common practice, granulomatous lung disease and pulmonary hypertension will be encountered.⁴⁻⁶ Both abnormalities are induced by the excipients found in the pills, rather than the drug itself. Even though granulomatous disease involving the pulmonary vasculature and interstitium is relatively common among injection drug users, the clinical consequences of these lesions are difficult to estimate, and the finding may often be overlooked.⁷ The practice of injecting crushed pills is much more common in some places than others, so the presence of granulomas, while diagnostically useful, cannot always be assumed. Most adult drug abusers practice polypharmacy; attempts at correlating specific drugs with certain types of lesions is a difficult, if not impossible exercise.

Earlier studies of heart disease in drug users must be interpreted with very great caution, particularly those studies where the diagnosis was not confirmed by toxicological testing. One study of 168 drug-related deaths found a 100% incidence of heart disease,⁸ but since toxicological findings were not known for all the patients, and since the limits of detection for drugs were far higher in the early 1980s than today, and since all of the patients were referred because they were suspected of having heart disease in the first place, not a great deal can be concluded about the real incidence of the problem.

Sudden unexpected death in young adults, aged 18 to 35 years, accounts for an important subset of drug-related deaths. A study of cases occurring over a 10-year period in Galway, Ireland, found that a large proportion, over one third, of sudden deaths in young adults were secondary to epilepsy, and/or chemical/drug poisoning. In total, these deaths amounted to 9% of the deaths occurring in the study population.⁹ In Australia, where the lifetime use of cocaine is rising, only 3% of the population over age 14 was using cocaine in 1991, but that number had increased to 4.5% in 1998, and cocaine accounted for 10% of all illicit drug-related deaths in that country. Most of these deaths appear to have been the result of acute myocardial infarction.¹⁰ Reliable statistics for the incidence of cocaine-related and/or heroin-related heart disease in the United States are not available.

2.3.2 Mechanism of Myocardial Hypertrophy

Even in the absence of solid epidemiological data, certain generalizations are possible. The hearts of chronic stimulant abusers, whether of cocaine or methamphetamine, or even MDMA, are enlarged, and often manifest changes consistent with the known effects of prolonged catecholamine excess. Myocardial hypertrophy in cocaine abusers has been confirmed by comparisons of cocaine abusers' electrocardiograms to those of age-sex-matched controls, to those of asymptomatic cocaine users in rehabilitation, and to cocaine users seeking treatment for chest pain.¹¹⁻¹³ Myocardial hypertrophy has been reported in separate, controlled, autopsy studies of cocaine, methamphetamine, MDMA, and ephedrine users.¹⁴⁻¹⁷ The increases are generally quite modest, averaging 10 to 11% over that predicted by standard nomograms.¹⁸

Molecular biologists have shown that stimulant-type drugs cause increases in the myocardial expression and activation of cAMP response binding protein, otherwise known as CREB. CREB is one of the transcriptional factors that regulate gene expression, mainly through the action of a large group of different kinases. These include protein kinase A, calcium calmodulin kinase II, and mitogen-activated protein kinase. All three can induce CREB phosphorylation at serine position 133.¹⁹ The result is increased myosin production and myocardial hypertrophy,²⁰ primarily because more calmodulin is produced. Calmodulin is a small, acidic protein. It binds to Ca²⁺-binding proteins and, in conjunction with calcium and other molecules, it acts as a second messenger, controlling diverse biochemical processes in many different cell types, not just myocytes. Calmodulin kinase II activity is required for normal atrioventricular nodal conduction,²¹ and calmodulin itself protects against structural heart disease.²² It appears that cocaine users develop myocardial hypertrophy

because cocaine directly activates calmodulin kinase II.²³ Whether the same process occurs in methamphetamine, ephedrine, or MDMA abusers is not yet known.

The hearts of heroin abusers generally do not show evidence of myocardial hypertrophy unless, of course, the abusers are simultaneously abusing stimulants, an increasingly common practice. It appears that heroin does not lead to CREB phosphorylation, at least not in the myocardium, although there is evidence for CREB activation in the brain.²⁴ Heroin abusers may not be uniquely subject to myocardial hypertrophy, but HIV-related disease is common among heroin users, as are a multitude of other “lifestyle” disorders such as hepatitis (types A, B, and C)^{25,26} and tuberculosis.²⁷ If one of these associated disorders leads to restriction of the pulmonary bed, and pulmonary hypertension, at least some degree of right ventricular hypertrophy is to be anticipated.

2.3.3 Consequences of Myocardial Hypertrophy

Left ventricular hypertrophy is the normal cardiac adaptation to a prolonged increase in arterial blood pressure or, at least, to the activation of the genes responding to a pressure increase. One of the earliest results of the pioneering Framingham Study was the clear demonstration that patients with electrocardiographic evidence of left ventricular hypertrophy are at increased risk both for sudden cardiac death and for acute myocardial infarction.²⁸ Hypertensive patients with left ventricular hypertrophy have substantially more premature ventricular beats than normotensives,²⁹ and even more than hypertensives who still have normal size hearts. Recent studies have shown that calmodulin-dependent mechanisms are responsible for both the increase in ectopy and for the occurrence of sudden death in cocaine users (and non-drug-using hypertensives), even in the absence of clinically apparent myocyte hypertrophy. Enlarged hearts are prone to QT dispersion (defined as the difference between the longest and shortest QT interval measured in each of the 12 leads of the cardiogram). Dispersion equates to electrical inhomogeneity; the greater the degree of dispersion, the higher the probability a reentrant type arrhythmia will occur.^{30,31}

The problem for death investigators is that changes in heart weight, amounting to less than 10% of predicted weight, are likely to go unrecognized at autopsy. The result is that a possible cause of death may be missed. Even if wall thickness is fastidiously measured, which is not always the case, a 10% increase is likely to go undetected. Small changes go unnoticed mainly because several different systems are used for determining normality. Some pathologists still believe that arbitrary cutoffs can be used: 380 or 400 g for men and 350 g for women. Others determine normality by using a formula; heart weights less than 0.4% of the body weight (0.45% for women) are considered normal.³² The most accurate approach is to use a nomogram based on a large series of autopsies. Several have been published, including the Mayo Clinic nomogram relating heart weight both to height and to weight.¹⁸ Any value more than 2 standard deviations above the predicted mean is considered abnormal (see Appendix III for copies of the nomogram). Unfortunately, the range is so wide that some hearts may wrongly be classified as normal.

2.3.4 Other Stimulant-Related Disorders

Reports of cardiomyopathy in cases where neither biopsy nor arteriogram was performed^{33–37} are difficult to interpret, and the diagnosis of cardiomyopathy in such cases should be considered unconfirmed; the underlying disease is as likely to be ischemic as to be drug mediated. The few reported cases of ephedrine-related cardiomyopathy fall into this category, although when cases have occurred, it has only been in abusers consuming massive amounts of ephedrine for prolonged periods.^{38–40} However, dilated cardiomyopathy, in the proven absence of ischemia, has been documented in methamphetamine abusers,⁴¹ and it seems likely that the reported number of new cases will increase.

When direct examination of the hearts of stimulant users has been performed, most of the observed changes appear to be related to catecholamine.^{42,43} Chronic catecholamine toxicity is a

well-recognized entity in humans and animals. In fact, norepinephrine “myocarditis” was first described nearly 50 years ago,^{44,45} and its histological features are indistinguishable from those seen in patients with pheochromocytoma. Contraction band necrosis is the earliest recognizable lesion in both humans and animals.⁴⁶

Several distinct features can be used to distinguish catecholamine-induced necrosis from ischemic necrosis. The most obvious is the distribution of the lesions. In ischemic injury, all cells supplied by a given vessel are affected, leading to a homogeneous zone of necrosis. In catecholamine injury, individual necrotic myocytes are to be found interspersed between normal cells, and the pattern of injury cannot be related to the pattern of blood supply.⁴⁷ Ischemic and catecholamine necrosis can also be distinguished by the arrangement of the myofilaments. In ischemia the myofilaments remain in register. In cases of catecholamine toxicity, the arrangement of the filaments is disrupted. In addition, a mononuclear, predominantly lymphocytic, infiltrate may be seen after 12 h (as opposed to the neutrophilic infiltrate seen during the initial phases of ischemic infarction). Necrotic myocytes are eventually reabsorbed and replaced by non-conducting fibrous tissues. After repeated bouts of necrosis, the myocardium becomes increasingly fibrotic, leading to systolic dysfunction and, more importantly, abnormal impulse propagation.⁴⁷

Biopsy findings in a group of cocaine users with recent onset of chest pain and congestive heart failure demonstrated changes very similar to those described above, with microfocal interstitial fibrosis evident in all cases.⁴³ Lymphocytic infiltrates were seen in only two of the cases, and there were no eosinophils present. Contraction band necrosis (CBN) is a prominent artifact of endomyocardial biopsies, so the presence of these lesions in biopsied drug users is impossible to assess, even though CBN may well be associated with cocaine use. In fact the first reports of CBN in cocaine users were published in the European literature in the 1920s. They were promptly forgotten for another 50 years, until they were rediscovered in a report that appeared in the *New England Journal of Medicine* in 1986.⁴⁸

A biopsy of one of the patients in the *New England Journal of Medicine* report did show eosinophilic myocarditis, but such cases are extremely rare and still reportable. In fact, there has only been one additional reported instance of cocaine-associated eosinophilic myocarditis in the last decade.⁴⁹ Even if a known cocaine user were found to have an eosinophilic infiltrate in his or her heart, it would more likely be the result of allergy to excipients mixed with the drug, than from the cocaine itself. The variety of excipients used to dilute cocaine and heroin is not tracked by any official agency (although it very likely is by some government agencies), and it clearly varies by location and drug origin. An Italian report, now more than a decade old, found that lidocaine and caffeine were the two agents most frequently used to adulterate cocaine. More recently, an assortment of medications has been detected in cocaine specimens, including multiple samples containing diltiazem.

Amphetamines seem to be associated with the same changes in the heart that are associated with cocaine abuse.^{50,51} The Japanese literature contains one report describing a long-term methamphetamine abuser who collapsed while being arrested. His heart was hypertrophied, but there was no evidence of myocardial disarray. Endocardial thickening, with increased numbers of elastic fibers, was apparent in all the ventricles and in the atria. There was also narrowing of the lumen of the AV nodal artery secondary to interstitial fibrosis and scar formation. The authors believed that compression of the nodal artery by scarring accounted for the individual's sudden death.⁵²

2.3.5 Myocardial Disease in Opiate Abusers

Distinctions between the hearts of opiate and stimulant abusers have become increasingly blurred. In the uncommon situation where an individual is a pure opiate abuser, morphologic changes are uncommon. Autopsy studies of heroin abusers done during the 1960s and early 1970s did not even mention the occurrence of heart disease.^{1,53} Clinical studies from that period are equally unrevealing. Among addicts admitted to Bellevue Hospital's general medicine service, the incidence of endocarditis was under 10% and no other cardiac disorders were even mentioned.³ Whether or

not opiates visibly damage the myocardium, undetectable interactions may be occurring at the molecular level. Randomized clinical trials published in 2005 showed convincingly that the mortality of patients with myocardial infarction increases when they are treated with morphine.⁵⁴ Why that should be is impossible to say.

Myocardial fibrosis is not uncommon in opiate abusers, but it probably just signifies concomitant stimulant abuse. Larger areas of fibrosis may represent zones of healed infarction, even if they were not diagnosed during life. Although a handful of case reports have appeared in the literature,^{55,56} there is no evidence that coronary artery disease is more common among heroin abusers than in the general population. Nonetheless, intravenous drug injectors, no matter what the drug, are prone to pulmonary hypertension as a consequence of granuloma formation in the pulmonary bed.⁵⁷ Rarely a talc granuloma may be seen in the myocardium.⁵⁸

Infectious disease now accounts for most of the changes seen in the hearts of drug abusers (see Chapter 2.4 for a discussion of endocarditis in drug abusers). HIV may involve the heart. The most common manifestations of HIV are dilated cardiomyopathy, myocarditis, pulmonary hypertension, pericardial effusion, endocarditis, and HIV-associated malignant neoplasm. Although highly active antiretroviral therapy (HAART) does prolong many patients' lives, it has no effect on the cardiac sequelae of HIV, which will continue to evolve without specific treatment.⁵⁹

There are also reports of myocardial infarction in young patients infected with HIV receiving protease inhibitors, raising concerns about premature arteriosclerosis and coronary artery disease in this patient group. It appears that metabolic alterations produced by antiretroviral therapy worsen the cardiovascular risk profile of patients infected with HIV.⁶⁰ When coronary artery disease occurs in an HIV-infected drug abuser, it is impossible to say whether it is a consequence of disease or addiction. Unfortunately, drug users continue to use drugs even after they are infected with HIV. As with coronary artery disease, in many cases it will also be impossible to tell whether sudden death in a drug user is related to the drug or to the virus. Some cardiotropic viruses can cause myocardial infarction and even myocarditis, but are detectable only by advanced DNA polymerase technology, a methodology beyond the reach of most medical examiners' offices.⁶¹

2.4 VALVULAR HEART DISEASE

Michael D. Bell, M.D.

District Medical Examiner, Palm Beach Medical Examiner Office, West Palm Beach, Florida

2.4.1 Infective Endocarditis

Although intravenous (IV) drug abuse is a recognized risk factor for infectious endocarditis, this complication is not a frequent complication among IV drug users. The incidence of infective endocarditis in IV drug abusers is estimated at 1.5 to 2.0 cases per 1000 IV drug abusers admitted to the hospital¹ or 1 to 20 cases per 10,000 IV drug users per year. IV drug abusers with infective endocarditis are more likely to be young men (average age = 29 years, M:F = 3:1) compared with non-addicts with endocarditis (average age = 50, M:F = 2:1).² The frequency of underlying heart disease in IV drug abusers with endocarditis is 26% compared with 60% of non-addicts with endocarditis. In a cohort of 85 IV drug abusers, echocardiography failed to detect any valvular vegetation consistent with endocarditis.³ Eight IV drug abusers had thickened or redundant leaflets (with or without prolapse) of the mitral, aortic, or tricuspid valve. Focally thickened leaflets of the mitral and tricuspid valves have been reported in other series of asymptomatic IV drug abusers who were examined by echocardiography.⁴ These subtle morphologic abnormalities may be the stratum upon which endocarditis builds. Most researchers agree that endothelial injury or damage initiates fibrin, platelet, and bacterial depositions that produce endocarditis.

In Dressler and Robert's series of 80 autopsied IV drug abusers with infective endocarditis, the tricuspid valve was involved in half of the victims compared with 15% of victims dying of acute endocarditis who did not use IV drugs.⁵ Why IV drug users are more likely to develop right-sided endocarditis than non-IV drug users is not known. Postulated factors include physical damage by injected particulate debris, especially if pills are crushed and then injected. Drug-induced pulmonary hypertension in IV drug abusers may cause increased right ventricular pressure and more turbulence flow, resulting in tricuspid valve injury. However, IV drug abusers can, and often do, have left-sided valve involvement. The aortic and mitral valves are involved in 25% and 20% respectively of IV drug abusers with infective endocarditis. Most cases of acute endocarditis in IV drug abusers are caused by *Staphylococcus aureus* as compared with other streptococcal species commonly responsible for endocarditis in those not injecting IV drugs.⁶ Outbreaks of methacillin-resistant *S. aureus* endocarditis in IV drug users have been reported in Detroit, Boston, and Zurich. Polymicrobial infection is seen in 8 to 9% of cases of infective endocarditis that involve IV drug abusers, while *Streptococcus viridans* causes right-sided endocarditis in 11% of IV drug abusers. Fungal, usually non-albicans *Candida* species endocarditis is usually superimposed on valves previously damaged by an earlier episode of bacterial endocarditis and usually has a more indolent clinical course. Other unusual pathogens causing endocarditis in IV drug abusers are summarized in Table 2.4.1.

Grossly, infective endocarditis is characterized by friable, white or tan vegetations found on the valve leaflets along the closure lines. Vegetations may be single or, more often, multiple. In one clinical series the mean vegetation size in IV drug abusers with acute right-sided bacterial endocarditis was 1.5 0.7 cm.⁶ The size, color, and appearance of the vegetations can vary, however. Streptococcal vegetations grow more slowly than staphylococcal vegetations, but may become larger. Fungal vegetations are usually larger than bacterial vegetations. Vegetations occur more often on the atrial side of the atrioventricular valves and on the ventricular side of the aortic or pulmonic valves. Suppurative bacteria such as *Staphylococcus* may cause valve perforation, resulting in acute valvular insufficiency. Infection may extend into the adjacent myocardium producing necrotic fistulas, aneurysms, or ring abscess (usually of the aortic valve). Further extension results

Table 2.4.1 Uncommon Pathogens in Endocarditis of Intravenous Drug Abusers¹¹

Group B <i>Streptococcus</i> (<i>Streptococcus agalactiae</i>) ¹²
Coagulase-negative <i>Staphylococcus</i>
Gram-negative bacteria (<i>Pseudomonas</i> , <i>Serratia</i> , <i>Kingella</i> , etc.)
<i>Corynebacterium</i> spp., <i>Neisseria sicca</i> , <i>Rothia denticariosua</i>
<i>Haemophilus</i> spp.
Erysipelothrix
Anaerobic bacteria (<i>Bacteroides</i> , <i>Veillonella</i> , <i>Eikenella</i> , <i>Fusobacterium</i> spp., <i>Clostridium</i> spp., etc.)
Fungi (<i>Candida</i> spp.)

Figure 2.4.1 Large necrotizing vegetations on the tricuspid valve of this 31-year-old addict who commonly injected drug subcutaneously (“skin popping”). Blood cultures were positive for *Streptococcus hominus*.

in pericarditis, found in 4 to 27% of cases of left-sided infective endocarditis.⁷ Involvement of the chordae tendinae may lead to rupture and valvular insufficiency. Tricuspid and pulmonic vegetations may embolize to the lungs, resulting in the formation of suppurative abscesses (Figure 2.4.1 and Figure 2.4.2). Perforation, indentation, or aneurysm of the valve cusp or chordae tendinae is presumptive evidence of healed endocarditis.

Microscopically, acute bacterial endocarditis is characterized by masses of fibrin, platelets, and polymorphonuclear leukocytes with bacterial colonies on the valve surface. Bacteria are less frequent after antibiotic treatment, and may not be demonstrable by Gram stain, even if present.⁸ Later, the microscopic appearance is characterized by organization with capillary proliferation, a mixed cellular infiltrate, and the formation of granulation tissue. If the individual survives, the lesions eventually heal by fibrosis and re-endothelialization. Calcification may be present in the healed lesions.

The clinical diagnosis of acute infectious endocarditis includes the acute onset of fever, chills, and heart murmur. Right-sided valve murmurs (as in IV drug abusers) may be less audible than left-sided valve murmurs because the reduced chamber pressures of the right heart produce less turbulence and less noise. Signs of early tricuspid insufficiency may be minimal with only an atrial or ventricular gallop and no murmur. Later, a systolic regurgitant murmur, louder with inspiration, appears. Large “v” waves in the neck veins and a pulsating liver are signs of severe tricuspid

Figure 2.4.2 The lung from the victim in Figure 2.4.1 has multiple suppurative abscesses and extensive dark red consolidation.

regurgitation.⁹ Confirmation of the diagnosis includes isolation of the causative organism from two or more blood cultures and identification of valvular vegetation by echocardiography. The criteria for the clinical diagnosis of infective endocarditis have recently been revised. Bacteremia is characteristic of endocarditis, and most IV drug abusers with endocarditis have positive blood cultures even after a few days of antibiotic treatment. True culture-negative endocarditis is rare in IV drug abusers, and negative blood cultures suggest another cause for their illness.

The occurrence of chest pain with dyspnea, along with characteristic abnormalities of the chest radiograph (multiple segmental infiltrates with lower lobe predilection), suggests septic pulmonary emboli from a right-sided valvular vegetation. Systemic embolization can occur in right-sided endocarditis from septic pulmonary vein thrombi, left-sided valvular involvement, or paradoxical embolization through a patent foramen ovale. Table 2.4.2 compares the clinical features of right-sided and left-sided endocarditis.¹⁰ Mortality in IV drug abusers with acute right-sided endocarditis varies from 4 to 14%.⁶

Table 2.4.2 Comparison of Right-Sided and Left-Sided Endocarditis

Right-Sided	Left-Sided
IV drug abusers most common	Congenital heart disease most common
<i>Staphylococcus aureus</i> most common	<i>Streptococcus viridans</i> most common
Occasional polymicrobial involvement	Polymicrobial involvement rare
Presents with pleuropneumonic symptoms	Symptoms from distal systemic embolization more common
10% of all infective endocarditis	90% of all infective endocarditis
Heart failure is unusual	Heart failure is common
Good prognosis with frequent cure after medical therapy	Poor prognosis with poor success rate using medical therapy
Surgery usually does not require immediate valve replacement	Surgery usually requires immediate valve replacement

The source of the infecting organisms is usually from the addict's own body (skin or mouth flora), or soft tissue infection at the injection site, not contaminants in the drugs or the drug paraphernalia.¹³ Cultures of heroin samples and drug paraphernalia have failed to demonstrate the presence of common pathogens.

2.4.2 Fenfluramine-Associated Regurgitant Valve Disease

Fenfluramine is a sympathomimetic amine chemically similar to amphetamine, but with less stimulant activity. Fenfluramine was a popular anorectic agent in the 1990s, prescribed alone or in combination with another sympathomimetic amine, phentermine. Prescriptions for these appetite suppressants exceeded 18 million in 1996. Fenfluramine's anorectic effect is thought to result from its ability to promote serotonin release and decrease brain re-uptake.

Connolly et al.¹⁴ described 24 women with regurgitant valve disease that had its onset after they took fenfluramine-phentermine ("fen-phen") for 1 to 28 months. One fifth of these women required valve surgery and one third developed pulmonary hypertension. Macroscopic features in the removed valves from these women included irregular nodular leaflet thickening, thickened and tethered glistening white leaflets, leaflets with "stuck on" or "onlay" plaques, and chordal fusion. Valve vegetations, commissural fusion, and annular dilatation were not seen. Microscopically, fibromyxoid plaques and nodules were seen to lie on top of the affected leaflet or encase the chordae tendinae. Myofibroblasts proliferated in the extracellular matrix. The onlay plaques are usually found to be superficial to the elastic fiber layer in the mitral valve. Ultimately these pathologic changes result in a thickened immobile regurgitant valve. Other pathologists have confirmed these findings.^{15,16} Later case control and meta-analysis studies,^{17,18} however, did not demonstrate as much clinically significant mitral valve disease as the original Connolly study, but by then, fenfluramine was already removed from the U.S. market.

2.5 LUNG DISEASE

Michael D. Bell, M.D.

District Medical Examiner, Palm Beach Medical Examiner Office, West Palm Beach, Florida

2.5.1 Pulmonary Effects and Pathology of Smoked Illicit Drugs

Heroin is usually smoked by heating a mixture of heroin and caffeine on foil, then inhaling the resultant vapor through a straw. Cocaine freebase or “crack” cocaine is also heated and the vapors inhaled, as is crystallized methamphetamine. Finally, dried *Cannabis sativa* is smoked as a cigarette, or in a pipe. Ascribing a specific pulmonary dysfunction or pathology to a specific drug is difficult, because drug users consistently smoke more than one drug. In one study of 100 heroin users, 88% smoked heroin, 79% inhaled cocaine, 71% smoked marijuana, and 98% smoked cigarettes¹ and had been, on average, for 26 years. These confounding factors must be considered before assigning causation of a specific pathology to a specific drug. Several review articles summarizing the pulmonary changes in drug users have been published.

Bailey et al.² performed an autopsy study of cocaine abusers’ lungs and found the most common changes were pulmonary congestion (88%), edema (77%), and acute/chronic alveolar hemorrhage (71%). Similar findings were reported by Murray et al.^{3,4} who found hemosiderin-laden macrophages in 35% (7 of 20) of the victims of cocaine intoxication and concluded that occult alveolar hemorrhage occurs more frequently in cocaine users than is clinically recognized. Murray also noted pulmonary artery medial hypertrophy in 20% (4 of 20) of cocaine abusers who had no histological evidence of foreign material embolization. The cause of the alveolar hemorrhage was thought to be ischemic damage to the capillary endothelium secondary to constriction of the pulmonary vascular bed after cocaine inhalation, or possibly a result of some direct toxic effect of cocaine on the capillary endothelium. Neither hypothesis is proved.

Hemosiderin-laden macrophages may be seen in bronchoalveolar lavage fluid or in bronchoscopy biopsy specimens. One cocaine abuser who presented with diffuse alveolar hemorrhage had no vasculitis, and electron microscopy did not demonstrate any disruption in the alveolar or capillary basement membranes.⁴ Pulmonary hemorrhage has not only been associated with alkaloidal “crack” cocaine smoking, but also with intravenous and nasal routes of administration.⁵ Pulmonary congestion in fatal cocaine intoxication is usually ascribed to the slow cessation of cardiac function associated with brain stem hypoxia during terminal seizures, or else to direct cocaine toxicity.

Figure 2.5.1 Abundant blood-tinged foam escapes from the end of the endotracheal tube in this drug abuser with pulmonary edema.

Fatal and nonfatal pulmonary edema (Figure 2.5.1) has been reported in cocaine smokers who have no obvious cardiac or central nervous system disease.⁵⁻⁸ In some of these individuals the pulmonary edema resolved without specific treatment, and chest radiographs have shown normal cardiac silhouettes. The hemodynamic status of patients with cocaine-associated pulmonary edema has never been studied. One patient underwent bronchoalveolar lavage and the lavage fluid was found to have an elevated protein level (four times normal), suggesting that the edema was due to altered alveolar capillary permeability.⁷ Bronchial biopsy usually has shown no histological abnormalities⁷ or only “mild interstitial inflammatory changes.”⁸

Pneumonitis, as defined by widening of the alveolar septae in the presence of a polymorphous infiltrate (lymphocytes, neutrophils, macrophages, eosinophils) or fibrosis, was seen in one fourth of the victims studied by Bailey et al.,² while Patel et al.⁹ have described a patient with bronchiolitis obliterans and organizing pneumonia (BOOP) associated with regular use of free-base cocaine during the weeks prior to the onset of his clinical symptoms (nonproductive cough, fever, dyspnea). An open lung biopsy revealed patchy bronchocentric interstitial and intra-alveolar chronic inflammation, with lymphocytes, macrophages, and few polymorphonuclear leukocytes and eosinophils; granulation tissue and collagen occupied bronchioles and adjacent alveolar ducts, but the blood vessels were normal. A hypersensitivity reaction to cocaine, or a cocaine adulterant, was the presumed cause. A similar mechanism also presumably explains the occurrence of “crack lung,” a clinical syndrome characterized by chest pain, hemoptysis, and diffuse alveolar infiltrates, a constellation of symptoms and signs seen only with smoking “crack” cocaine (Figure 2.5.2). Finally, 11% of the cocaine fatalities have polarizable birefringent material, usually talc, within the lungs. Most of these victims were, not unexpectedly, intravenous drug abusers.^{10,11} Other diluents, such as starch and cellulose fibers, may be recognized by their typical pattern of birefringence.

Figure 2.5.2 Intra-alveolar macrophages contain coarse black pigment in a crack cocaine abuser.

Sometimes users of cocaine freebase, or “crack” cocaine, forcefully blow smoke into another user’s mouth in order to augment the drug’s effect (more absorption). Smokers also prolong the Valsalva maneuver in order to avoid expiring the precious cocaine smoke. The resulting increased intra-alveolar pressure ruptures the alveolar walls, allowing air to dissect along the perivascular tissues, into the mediastinum and surrounding cavities. This basic mechanism has been responsible for all types of barotrauma including pneumothorax, pneumo-mediastinum,^{12–14} pneumo-pericardium,¹⁵ pneumoperitoneum,¹⁶ and subcutaneous emphysema. In the few cases to be reported,¹⁷ where the duration of cocaine use prior to clinical symptoms was accurately known, patients freebased cocaine for 8 to 12 h and snorted cocaine for 1 h. Thus, it seems unlikely to occur on the first puff, but the possibility cannot be dismissed either. The clinical course of cocaine-associated barotrauma is generally nonfatal. This barotrauma is a nonspecific finding; it has been described in marijuana smokers,¹⁸ and presumably occurs in smokers of methamphetamine as well.

Individuals with asthma who smoke heroin and cocaine are subject to acute severe exacerbation of their asthma.^{19–22} There is nothing to distinguish nondrug-related asthma from asthma occurring secondary to drug usage, although bronchial mucus plugs and pulmonary hyperinflation were observed at autopsy in 64.7% of those with asthma who also had a history of drug or alcohol abuse.²³ Sudden death in this population may be the result of status asthmaticus, although it could also be the result of cocaine’s arrhythmic effects, direct or indirect in the setting of an acute asthmatic attack. Insufflation of cocaine hydrochloride has also been associated with near-fatal status asthmaticus.²⁴ Blackened sputum and pulmonary cytologic specimens with excessive carbonaceous material are highly suggestive of crack cocaine use.²⁵ As crack is smoked, a dark, tarry residue forms on the inside of the pipe’s bowl and barrel. Many smokers consider this residue to be concentrated cocaine and they scrape it free, reheat it, and vigorously inhale it. As a result, coarse, intracellular black particles, and intra-alveolar macrophages filled with black pigment, may be seen in crack cocaine abusers at autopsy (Figure 2.5.2).

The long-term pulmonary effects and pathology of smoking cocaine are unknown. Pulmonary function studies are confounded by the fact that cocaine smokers also smoke tobacco and marijuana in addition to cocaine. Cocaine smokers have a reduced diffusing capacity of carbon monoxide, but no spirometric abnormalities have been demonstrated.²⁶ Marijuana and tobacco smoking both produce similar changes in the bronchial mucosa; the histopathological changes include basal and goblet cell hyperplasia, squamous cell metaplasia, basement membrane thickening, inflammation, and increased nuclear variation and N/C ratio. Cocaine smoking does not produce these changes to the degree seen in the former groups.

Figure 2.5.3 Abundant birefringent material lies within this pulmonary artery thrombus from an intravenous drug abuser (Hematoxylin and eosin, polarized light, original magnification 80×).

2.5.2 Complications of Intravenous Drug Abuse: Granulomatous Pneumonitis/Arteriopathy

Intravenous drug abusers may crush oral medications and suspend them in water for intravenous injection. Methadone²⁷ and propoxyphene²⁸ are examples of oral drugs abused in this fashion. Pill filler material contains insoluble particles. Once these insoluble particles reach the lung, they cause thrombosis, granulomatous inflammation, and fibrosis. The granulomas have numerous multinucleated giant cells and contain birefringent foreign material (Figure 2.5.3; Table 2.5.1). When abundant, the granulomas and foreign material impart a granular texture to the lung. In addition to their morphology, the foreign particles can be identified by selected-area electron diffraction and energy dispersive x-ray analysis. The functional consequence of these lesions is often pulmonary hypertension with its accompanying complications, including cor pulmonale and sudden death. In nonfatal cases, patients may present with dyspnea, mild hypoxemia, and diffuse micronodules apparent on their chest radiographs. Gallium scanning can be used to demonstrate reduced diffusion across the parenchyma capacity; serum angiotensin-converting enzyme concentration in the lung is also elevated. The granulomatous and fibrotic reaction may be in the interstitium, presumably because the particles migrate through the arterial walls²⁹ and vascular remodeling occurs. Thromboembolic vascular remodeling produces recanalized arteries and intimal fibrosis. Plexiform and angiomatoid vascular lesions may also be seen. Large fibrotic pulmonary masses have been described with huge particle counts and occasional giant cells. The fibrotic masses are usually bilateral, asymmetric, and confined to the middle and upper lung fields. These are similar to the progressive massive fibrosis seen in complicated pneumoconiosis.^{30–32}

Pulmonary hypertension due to pulmonary artery thromboses has been reported to result from the repeated intravenous injection of “blue velvet,” a mixture of paregoric and tripeleminamine (Pyribenzamine) tablets,^{33,34} although this practice no longer seems very popular. Methylphenidate (Ritalin) tablets contain talc (magnesium silicate) and cornstarch, which can cause pulmonary hypertension and sudden death, often within 6 to 7 months of abusing the drugs. It is a practice in some areas to use Ritalin tablets as stimulants to counteract the sedative effects of methadone maintenance in addicts.

While cornstarch can cause foreign body granulomas to form, the reaction is generally milder and less frequent than the granulomatous inflammation caused by talc,³⁵ which is irritating to tissues and may cause thrombosis with occlusion of pulmonary arterioles and capillaries, and a granulomatous inflammation with parenchyma fibrosis.²⁹ The end result is a restrictive lung disease with

Table 2.5.1 Common Foreign Material Found in the Lungs of IV Drug Abusers

Foreign Material	Drugs	Appearance	Notes
Talc	Methylphenidate (Ritalin) Methadone Tripeleonnamine HCl (Pyribenzamine) Propoxyphene (Darvon) Meperidine (Demerol) Benzedrine Dilaudid	Birefringent refractile crystalline needles 5–23 μm long or plates, colorless or pale yellow on H & E	Most common type of foreign material
Cornstarch	Barbiturates Paragoric Tripeleonnamine HCl (Pyribenzamine) Pentazocine (Talwin)	Birefringent refractile 8–12 μm round particles of varying size, colorless on H & E, form “Maltese cross” with polarized light, PAS+, diastase resistant	Often seen with talc particles
Microcrystalline cellulose	Pentazocine (Talwin) Methaqualone (Quaalude) Percodan Acetaminophen/aspirin with codeine Phenobarbital	Large (10–250 μm), irregular birefringent crystals, pale gray on H & E, PAS+ diastase resistant, Congo red+, methenamine silver+	
Cotton fibers	Heroin and other IV drugs	Refractile, birefringent small filaments, ring-shape or curvilinear on cross-section, very pale blue on H & E	
Crospovidone	Hydromorphone, propoxyphene	100 μm basophilic globular or coral-shaped mass; does not polarize; seen with H & E, mucicarmine, Congo Red, and Movat stains	

impaired oxygen transfer across the alveolar-capillary membrane and pulmonary hypertension. The pulmonary arteries may have multiple intravascular and perivascular foreign body granulomas filled with birefringent talc. The pulmonary arteries may also have medial hypertrophy, fibrointimal hyperplasia, and angiomatoid lesions (Figure 2.5.4).^{36,37}

Pulmonary emphysema has been described in a subgroup of intravenous drug abusers who inject methylphenidate (Ritalin-SA). These patients present, complaining of dyspnea, at an average

Figure 2.5.4 Angiomatoid lesion with birefringent talc in an intravenous drug abuser (Hematoxylin and eosin, polarized light, original magnification 80 \times).

Figure 2.5.5 This sectioned lung has multiple abscess cavities. The victim was a 31-year-old cocaine “skin popper.”

age of 36 years. All have moderate to severe airflow obstruction with hyperinflation on chest radiography. The bullae are often seen in the lower lobes and the disease may mimic the emphysema seen in alpha-1-antitrypsin deficiency. Morphologically, there is panacinar emphysema with no interstitial fibrosis and variable degrees of pulmonary talc granulomatosis.³⁸

2.5.3 Aspiration Pneumonia

Alcoholism is a common predisposing condition for aspiration pneumonia. Aspiration of orogastric material (bacteria, acid, food, including milk, and charcoal-lavage material) can also occur in victims rendered unconscious by drugs directly (narcotics) or indirectly by drug-induced seizures (cocaine). The posterior segments of the upper lobes or superior segments of the left lower lobe are involved when the victim is recumbent during aspiration. The basal lung segments are affected when the victim is upright and the anterior segment of the middle lobe is involved when the victim is prone or inclined forward. Gastric acid can produce bronchiolitis, hemorrhagic edema, and diffuse alveolar damage if the agonal period is prolonged or delayed. Microscopically, gastric acid aspiration produces a distinctive bronchocentric pallor of the pulmonary tissues. Fluid contaminated with *Streptococcus pneumoniae* or *Klebsiella pneumoniae* characteristically produces subpleural pneumonia with hemorrhagic edema.³⁹ Aspiration pneumonia often is found to consist of a mixture of both aerobic and anaerobic bacteria. Striated muscle and vegetable fibers can be seen within the bronchioles and alveoli microscopically. Necrotizing bacteria may produce lung abscesses. Septic thromboemboli from tricuspid valve endocarditis can also produce multiple lung abscesses and pneumonia in the intravenous drug abuser (Figure 2.5.5 and Figure 2.5.6).

Figure 2.5.6 The victim in Figure 2.5.5 had acute bacterial endocarditis of the tricuspid valve with septic thromboemboli.

2.6 DISORDERS OF THE CENTRAL NERVOUS SYSTEM

Michael D. Bell, M.D.

District Medical Examiner, Palm Beach Medical Examiner Office, West Palm Beach, Florida

2.6.1 Alcohol Related

Marchiafava-Bignami¹⁻³ disease is a demyelinating disorder affecting the corpus callosum. It was first described in malnourished Italian men who drank cheap red wine. It has since been described in other countries and as occurring with other alcoholic beverages. Grossly, there is a discolored or partially cystic demyelinated region in the genu and body of the corpus callosum with sparing of the thin fibers along the dorsal⁴ and ventral surfaces of the corpus callosum. The optic chiasm and anterior commissures may also be involved. The lesion is bilateral and symmetric with sparing of the gray matter. Microscopically, there is demyelination sparing of the axon cylinders. The number of oligodendrocytes is reduced. Lipid-laden macrophages are often abundant.

Central pontine myelinolysis (CPM) is a demyelinating disorder of the central basis pons that was first described in malnourished alcoholics by Adams.⁴ Patients with CPM experience a sudden change in mental status, flaccid quadriplegia with hyperreflexia, pseudobulbar palsy, and an extensor plantar response unless coma obscures these signs. CPM is associated with the rapid correction or overcorrection of hyponatremia⁵ and the symptoms appear a few days (average 6 days) after overcorrection with intravenous sodium leads to a rise of at least 20 mmol/L. Grossly, victims will be found to have a discolored, finely granular demyelinated zone in the central basis pontis, with sparing of the tegmentum, ventral pons, and corticospinal tracts (Figure 2.6.1).⁶ Extrapontine myelinolysis has become more recognized.⁷ The demyelinated area varies from a few millimeters to the entire basis pontis and may be triangular, diamond, or butterfly shaped. Microscopically, there is demyelination with relative preservation of axon cylinders and neurons. Axonal spheroids are commonly observed. Acute lesions contain lipid-laden macrophages, but no other inflammatory cells. Oligodendrocytes are reduced or absent and reactive astrocytes are present.

Cerebellar degeneration of alcoholics is clinically manifested by truncal instability, lower extremity ataxia, and wide-based gait, symptoms appearing gradually over months or years.³ The pathogenesis is still unknown and may be due to the direct toxic effect of alcohol or to thiamine deficiency, or from rapid correction or overcorrection of hyponatremia similar to central pontine

Figure 2.6.1 Discolored granular zone of myelinolysis in the central pons of this 28-year-old alcoholic who was treating aggressively for hyponatremia.

myelinolysis. Grossly, the folia of the rostral vermis and anterosuperior cerebellar hemispheres are atrophic and shrunken with widened interfolial sulci. A sagittal section through the vermis rather than the usual coronal sectioning best demonstrates this. Microscopically, the folial crests are more severely affected than the depths of the interfolial sulci, which help to distinguish the changes from those seen in anoxic-ischemic injury. There is Purkinje cell loss, patchy granular cell loss, molecular layer atrophy, and gliosis with Bregmann glial proliferation.

Acute alcohol intoxication can cause death due to central cardiopulmonary paralysis.³ While blood ethanol concentrations over 450 to 500 mg/dl are usually considered lethal, there is considerable variability due to tolerance. Children are considered more susceptible to the lethal effects than are adults. Cerebral edema may be present or the neuropathologic examination may be normal. Delirium tremens or withdrawal seizures are not associated with any specific neuropathologic abnormalities.⁸

Chronic alcohol use may be associated with cerebral atrophy, although this is a disputed effect of alcoholism.³ The cerebral atrophy thought to be a result of chronic alcoholism involves the upper dorsolateral frontal lobes, but may extend inferiorly to the inferior frontal gyri and posteriorly to the superior parietal lobule.¹ There is mild ventricular enlargement. Microscopic changes are not specific. This type of cerebral atrophy may be associated with a dementia that is potentially reversible at its early stages.⁹

Fetal alcohol syndrome is a constellation of birth defects found in children of alcohol-abusing mothers. It is the most common cause of birth defects associated with mental retardation. Other clinical manifestations include irritability, seizures, hypotonia, and cerebellar dysfunction. The neuropathology findings are nonspecific and include microcephaly, compensatory hydrocephalus, neuroglial heterotopia of the ventricles or leptomeninges, and atrophy or hypoplasia of the cerebellum or centrum semiovale.^{3,10}

The autopsy manifestations of Wernicke's encephalopathy (gaze paralysis, ataxia, nystagmus, and mental confusion) and Korsakoff psychosis (retrograde amnesia, impaired short-term memory) seen in alcoholics¹¹ include petechiae and pink discoloration of the mammillary bodies (Figure 2.6.2).³ The morphologic features (seen in 1.7 to 2.7% of consecutive autopsies) include petechiae and pink discoloration of the mammillary bodies (Figure 2.6.2), hypothalamus, periventricular region of the thalamus, periaqueductal gray matter, and beneath the floor of the fourth ventricle.¹ The lesions are bilateral and symmetric when present. These gross features are seen in only 50% of acute cases;¹² therefore, microscopic examination is essential. The lesions vary with the stage and severity of the deficiency. Acute lesions consist of dilated, congested capillaries with perivascular ball and ring hemorrhages and ischemic neuronal changes (Figure 2.6.3). Chronic lesions have vascular endothelial cell swelling and proliferation and gliosis. Affected blood vessels may have irregular or bead-like swellings.

2.6.2 Drug Related: Excited Delirium

Excited delirium is a drug-induced delirium or psychosis accompanied by agitation, and hyperthermia, and often ending with respiratory arrest and sudden death. Cocaine is the drug most often implicated in this syndrome,¹³ but amphetamines have also been implicated in some cases. The syndrome is not due to any contaminants ingested along with the drug.

Chronic cocaine users have increased synaptic dopamine uptake in the ventral striatum. Victims of fatal cocaine-associated excited delirium, however, do not show this increase. Cocaine abusers also have increased serotonin transporter upregulation in dopaminergic areas of the brain. Serotonin is thought to modulate dopamine transmission. Some researchers believe that victims of fatal cocaine-associated excited delirium have a distinctive receptor phenotype differing from that of chronic cocaine users without excited delirium. The pathogenesis of cocaine-induced excited delirium is unknown. One hypothesis is that cocaine initially elevates brain dopamine levels causing the delirium. This cocaine-induced brain dopamine elevation has been demonstrated in animals.¹⁴

Figure 2.6.2 Coronal section of cerebrum demonstrates the mammillary body hemorrhage in Wernicke–Korsakoff syndrome.

Figure 2.6.3 Ball hemorrhage, capillary proliferation, and gliosis are present in this alcoholic with Wernicke encephalopathy (Hematoxylin and eosin, original magnification 20 \times).

Chronic cocaine use reduces brain dopamine metabolism¹⁵ potentiating the effect of cocaine on brain dopamine levels. As the cocaine concentration falls, brain dopamine falls triggering the syndrome, which is similar to the neuroleptic malignant syndrome (NMS) in Parkinson's disease or in patients withdrawn from levodopa, a dopaminergic drug. Some authors consider cocaine-induced psychosis as a variant of NMS in which patients also have hyperthermia, autonomic instability, and delirium (Table 2.6.1). NMS is characterized by diffuse muscular rigidity, but this is not seen in cocaine-induced excited delirium. One author has suggested that akinesia of the respiratory muscles may be the fatal mechanism of sudden death in these victims.¹⁶

There are no specific gross or microscopic findings in victims dying of cocaine-induced agitated delirium. A post-mortem core body temperature, if taken soon after death, will be elevated. A thorough post-mortem examination is essential to rule out other causes of sudden death. Cocaine and its metabolites must be present in toxicology specimens. Victims dying of agitated delirium have post-mortem blood cocaine concentrations (average = 0.6 mg/L with range of 0.14 to 0.92 mg/L) that are ten times lower than those concentrations in victims of cocaine overdose.¹⁷

Agitated delirium may occur following cocaine ingestion by all routes of administration (snorting, smoking, injection), but never after just chewing coca leaves. The majority of victims are men. Soon after cocaine ingestion, the person becomes paranoid, delirious, and aggressive. The victim

Table 2.6.1 Comparison between Neuroleptic Malignant Syndrome and Cocaine-Induced Agitated Delirium

Symptom	NMS	Cocaine Delirium
Hyperthermia	++	++
Delirium	++	++
Agitation	+	++
Akinesia/rigidity	++	—

Note: ++ = present in almost all cases; + = present in many cases; — = may occur late during syndrome.¹⁶

is often seen running, yelling, breaking glass and overturning furniture, disrobing, and hiding. Witnesses report that the person has unexpected strength. The victim often becomes calm and quiet before having a cardiopulmonary arrest, often during police custody or medical transport. This disorder is frequently accompanied by sudden death. Restraint procedures that could compromise respiration should be avoided. The restrained person should be closely observed, especially after the agitation subsides.¹⁸

2.6.3 Drug-Induced Cerebrovascular Disease

Drug-induced cerebrovascular disease or stroke is any nontraumatic intracerebral hemorrhage (including subarachnoid hemorrhage) or cerebral infarction that results directly or indirectly from drug ingestion. An accurate clinical history and/or positive toxicologic testing are needed to corroborate the recent drug ingestion. In all, 47% of patients less than 35 years old who present with an acute stroke have drug use as a predisposing condition.¹⁹ Clinically, a patient with cerebrovascular disease presents with sudden loss of function, neurologic deficit, and involvement of the corresponding vascular supply that occurs within minutes or rarely hours after drug ingestion. If the blood vessel is occluded through pharmacological vasoconstriction or vasospasm, ischemia and infarction occurs. If the vessel is damaged, hemorrhage results.

Cocaine is frequently associated with intracerebral hemorrhage.^{20–24} Other stimulant drugs including amphetamine,^{19,25} phenylpropanolamine,²⁶ phencyclidine,²⁶ pseudoephedrine,²⁶ and methylphenidate,^{19,26} have all been associated with intracranial hemorrhage.

Cocaine blocks the uptake of catecholamines at adrenergic nerve endings, potentiating sympathetic responses, leading to a dose-dependent elevation of arterial pressure and heart rate in humans²⁷ and dogs.²⁸ Amphetamine and methamphetamine can also produce transient hypertension and tachycardia. Researchers postulated that intracerebral hemorrhage occurs because of sudden marked elevation in systemic blood pressure in susceptible persons with preexisting vascular malformations. This would include such disorders as arterio-venous malformations, berry aneurysms,²⁹ or Charcot–Bouchard microaneurysms in hypertensive individuals.

In half of patients with cocaine-associated intracerebral or subarachnoid hemorrhage, no demonstrable structural lesion is identified.^{30–32} Another postulated mechanism of intraparenchymal hemorrhage in cocaine users is acute increased cerebral blood flow into an area of ischemia produced by prior cocaine-induced vasoconstriction.³³ Interestingly, intrauterine exposure to cocaine does not influence the prevalence or severity of intraventricular hemorrhage in the preterm infant.³⁴

Cocaine can cause cerebral infarction by arterial thrombosis, arterial embolism, arterial spasm, and circulatory compromise with secondary cerebral hypoperfusion. In the latter case, cocaine can cause acute myocardial infarction or ventricular arrhythmia resulting in hypotension and secondary cerebral hypoperfusion. The middle cerebral artery is most commonly affected with resulting sudden paraplegia.³⁵ The anterior cerebral, posterior cerebral, and basilar/vertebral arteries can also be affected resulting in a variety of clinical signs and symptoms (Figure 2.6.4 and Figure 2.6.5). Most victims develop symptoms suddenly, within 3 h of cocaine ingestion. Other victims wake up with

Figure 2.6.4 There is an occlusive thrombus in the basilar artery of this 28-year-old cocaine addict.

Figure 2.6.5 There is an irregular zone of infarction in the basis pontis of the victim in Figure 2.6.4. He was found comatose at home.

the neurologic deficit after heavy drug use the previous evening. Cannabis has recently been implicated in causing multiple nonfatal ischemic strokes in a 36-year-old man with no other risk factors. The mechanism for cannabis-induced stroke is unknown. No matter how convincing the case report, causation is established only by randomized clinical trials or, as in this case, with a nested case control study. Such studies are lacking.

The most common sites of cocaine-induced intracerebral hemorrhage are the cerebral hemispheres (57%) followed by the putamen (18%), and subarachnoid and intraventricular sites (Figure 2.6.6 and Figure 2.6.7). Cocaine-induced subarachnoid hemorrhage is usually due to rupture of a preexisting arterio-venous malformation or berry aneurysm of the cerebral arteries³⁵ (Figure 2.6.8). In a recent retrospective study from San Diego, 21% of victims dying from ruptured berry aneurysms had cocaine or methamphetamine (or both) in their post-mortem blood.³⁶ This was higher than the 5% incidence of cocaine or methamphetamine intoxication in all adult autopsies from the same jurisdiction.

If no vascular malformation is found to explain the subarachnoid hemorrhage in a drug addict, one must consider a traumatic cause for the subarachnoid hemorrhage (such as extracranial vertebral artery laceration³⁷) before blithely ascribing it to cocaine or another stimulant. Intraparenchymal hemorrhage due to cocaine use can occur in sites typical of patients with hypertension-related

Figure 2.6.6 This 35-year-old woman developed an acute intracerebral hematoma after cocaine use.

Figure 2.6.7 This brown slit-like cavity in the frontal white matter is all that remains of a previous cocaine-induced intracerebral hemorrhage.

intracerebral hemorrhage. The blood vessels, when examined, are usually normal both on gross and microscopic exam.³⁸ Charcot–Bouchard microaneurysms, or lipohyalinosis, are typically seen in hypertensive cerebral hemorrhage³⁹ and are not seen in drug-induced intracerebral hemorrhage. Patients are usually in their third to fifth decades of life with both men and women affected equally. Intracerebral hemorrhage occurs after snorting, smoking, or injecting cocaine. The time between drug use and symptom onset is usually within 3 h, but can range from immediate to 12 h. Most patients present with acute headache or in coma. Confusion is a less frequent presenting symptom. There is 36% mortality in patients who present to the emergency room with acute stroke strongly linked to recent drug use.¹⁹

2.6.4 Drug-Associated Cerebral Vasculitis

Cerebral vasculitis has been associated with cocaine, ephedrine, and amphetamine use. The association between cerebral vasculitis and cocaine use is tenuous and supported by a only few (eight) case reports, some of which have only angiographic evidence (“beading” or segmental

Figure 2.6.8 Subarachnoid hemorrhage in cocaine abusers is often due to a berry aneurysm that ruptures from the sudden blood pressure elevation caused by cocaine.

arterial narrowing) of vasculitis with no histological confirmation (Table 2.6.2).^{40,41} Since “beading” is considered by many to be a sign of vasospasm, the causation argument becomes circular. The remaining case reports do show histological evidence of vasculitis, but no angiographic narrowing or other abnormalities.^{42–45} Half of the victims presented with encephalopathy and coma without intracranial hemorrhage or infarction. The other half presented with intracerebral hemorrhage or cerebral infarction. Transient ischemic attacks (TIA) with multimodal segmental arterial stenosis on angiography have been reported in chronic cocaine users.⁴⁶ All these patients were young (mean age = 28 years with age range = 22 to 36) with multiple routes of drug administration used (nasal insufflation, smoking, intravenous injection). Histological examination demonstrated acute and chronic small vessel inflammation. Four cases had lymphocytic infiltration in the cerebral blood vessels. Two cases had polymorphonuclear leukocyte infiltration in the small arteries and venules of the brain. No giant cells or granulomas were seen in any case. The pathogenesis of cocaine-associated cerebral vasculitis remains unknown. Methamphetamine and structurally related drugs have reportedly caused necrotizing cerebral vasculitis.

2.6.5 Drug-Induced Seizure Disorder

Drug-induced seizures are, by definition, seizures that occur after the ingestion of a drug, that are not caused by other pathologic processes (intracranial hemorrhage or blunt head trauma). An accurate clinical history or positive toxicology testing should corroborate actual ingestion of the drug.

Cocaine has been reported to lower the threshold for seizures and commonly does cause seizures.⁴⁷ In one series of patients with seizure activity as the primary admitting diagnosis, cocaine was the most common drug of abuse detected.⁴⁸ At least in this series, cocaine-induced seizure was found to be more likely brief and self-limiting, compared to seizures caused by the other drugs of abuse (amphetamine, methamphetamine, phencyclidine, and sedative-hypnotic withdrawal). Seizures may also initiate a terminal cardiac arrhythmia, a theory that has gained more acceptance, but the suggestion has yet to be proved.^{49,50}

Fatal seizures associated with cocaine use have been reported.⁵¹ There are no specific gross or microscopic neuropathologic findings in fatal cocaine-induced seizure victims. Tongue contusions are nonspecific findings in patients who die of terminal seizures (Figure 2.6.9).

Table 2.6.2 Reported Cases of Cocaine-Associated Vasculitis

Report	Age/Sex	Route	Clinical syndrome	Angiogram	Time interval	Pathology	Outcome
Kaye, 1987	22 M	Nasal	Cerebral infarct	Beading, occlusion, narrowing	Unknown	None	Improvement with steroids
Klonoff, 1989	29 F	Smoke	ICH	Beading, narrowing	Unknown	None	Stabilized after hematoma removed
Krendel, 1990	36 M	Smoke	Weakness, dysarthria, confusion	Occlusion, narrowing	3.5 weeks	Acute vasculitis, small cortical vessels, cortical infarct with multinucleated giant cells	Improvement with steroids
Krendell, 1990	31 F	Smoke, IV	Coma, cerebral edema	Normal	42 days	Lymphocytic infiltration, small vessels and larger vessel normal, no granulomas, multiple cystic, necrotic, and gliotic areas in white matter with multinucleated giant cells	Death
Fredericks, 1991	32 M	Nasal, IV	Confusion, ataxia	Normal	13 days	Lymphocytic infiltration, small vessels and endothelial swelling	Improvement with steroids
Morrow, 1993	25 F	Nasal	Seizure, coma	Not done	5 days	Lymphocytic infiltration in small vessels of cortex and brainstem, small infarcts, cerebral edema with diffuse encephalomalacia	Death
Merkel, 1995	32 M	Nasal	ICH	Normal	2 days	Non-necrotizing leukocytoclastic vasculitis, neutrophils and mononuclear cells in venules	Improvement without steroids
Merkel, 1995	20 M	Nasal	ICH	Narrowing	<6 months	Neutrophil infiltration and fibrinoid degeneration in small arterioles and veins	Partial recovery

Figure 2.6.9 This cross section of tongue demonstrates the contusions that may be seen in drug-induced seizures.

Cocaine-induced seizure is a common neurologic complication (2.3 to 8.4%) of cocaine users who present with seizures to the emergency room⁵² that affects both men and women.⁵³ The average age is 27 years with a range of 17 to 42 years. Seizures occur after snorting, smoking, or injecting cocaine. The seizures are usually generalized, tonic-clonic, isolated, and self-limiting. They usually last less than 5 min and can occur with first-time and chronic cocaine users. The interval between cocaine ingestion and seizure onset varies from minutes to 12 h. In one emergency room study, 11 of 137 patients (8%) with cocaine intoxication presented with seizures as their chief problem and none died.⁵²

2.6.6 Drug-Induced Movement Disorders

Parkinson's syndrome has been reported in addicts who receive the synthetic meperidine analog contaminated with MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine). MPTP is produced during the careless synthesis of MPPP (1-methyl-4-phenyl-4-propionoxypiperidine) in clandestine laboratories. Neurotoxic symptoms include resting tremor, rigidity, bradykinesia, and other signs and symptoms of parkinsonism. Neuropathologic examination has demonstrated substantia nigra degeneration confined to the zona compacta. There is astrocytosis, focal gliosis, and deposition of extraneuronal melanin pigment.⁵⁴ It has been reported that MPPP contaminated with MPTP causes a Parkinson's syndrome within days of inject.⁵⁵ MPTP-induced Parkinson's syndrome can also result from snorting the drug.⁵⁶ The severe rigidity observed in MPTP-induced parkinsonism has been implicated in the asphyxiation death of one victim who was unable to move his head from a suffocating posture.⁵⁷ Post-mortem neuropathological examination of this individual also revealed severe neuronal loss in his substantia nigra. Cocaine use also has been associated with movement disorders. This may be related to the fact that concentrations of alpha-synuclein, a pre-synaptic protein found in Lewy bodies in Parkinson's disease, are increased in the midbrain dopamine neurons of chronic cocaine abusers.

2.6.7 Drug-Induced Anoxic Ischemic Encephalopathy

Abused drugs commonly produce anoxic-ischemic encephalopathy.⁵⁸⁻⁶⁰ This can occur from insufficient oxygen reaching the blood from the lungs, insufficient oxygen carriage, or inadequate cerebral blood perfusion. This is a common mechanism in drug abusers who have a delayed death after drug intoxication. In the older literature on fatal heroin overdose, cerebral edema with

increased brain weight was observed in nearly 90%. This finding conflicts with the author's own experience, where most cases of fatal heroin intoxication manifested neither cerebral edema nor increased brain weight.

The morphology of anoxic-ischemic encephalopathy is variable in its affect on different parts of the brain. In the gray matter, the watershed zones are commonly affected with laminar necrosis involving lamina zones III, V, VI. The h1 segment (Sommer's sector) and end plate in the hippocampus, are commonly involved. Other vulnerable sites include the Purkinje cells of the cerebellum, the caudate, and the putamen. The brain is often swollen and soft with a pale or dusky gray matter. Laminar necrosis may be apparent if sufficient time has elapsed between the time of anoxia and death. Microscopic changes are not recognizable until 6 to 8 h after the anoxic-ischemic insult. The affected neurons become shrunken with eosinophilic cytoplasm and nuclear pyknosis, and gradually disappear. There is also nonspecific capillary proliferation, with endothelial swelling, spongiform change, and gliosis in the affected neuropil. Hypoxic injury to the cerebral white matter with glossy softening and loss of myelin (hypoxic leukoencephalopathy) is less commonly seen in drug overdoses where death is delayed.

2.6.8 Drug-Associated Central Nervous System Infections

Primary fungal cerebritis due to *Rhizopus* has been reported in cocaine,⁶¹ heroin,^{62–66} and amphetamine⁶⁷ users with no other systemic foci identified at autopsy. Victims are usually men in their third or fourth decades of life. They present with hemiplegia, facial weakness, and headache. The brain lesions are usually multiple with frequent bilateral involvement of the basal ganglia. The phycomycoses are angiotrophic fungi that commonly occlude and invade the cerebral blood vessels causing hemorrhagic infarcts. Fungal cerebritis or meningitis has been reported in intravenous drug abusers (Figure 2.6.10 and Figure 2.6.11) with human immunodeficiency virus (HIV) infection. In addition to fungal cerebritis, HIV-infected intravenous drug abusers can develop a large variety of central nervous infections and neoplasms (Table 2.6.3), thereby fulfilling the criterion for acquired immunodeficiency syndrome (AIDS). Intravenous drug abusers with valvular endocarditis may develop central nervous system complications from emboli, both septic and bland infarction, which may affect a single or multiple vessels. The resultant lesions may be ischemic or suppurative, resulting in septic or aseptic meningitis, brain abscess, or encephalopathy.⁶⁸ This is more likely to occur with left-sided valvular endocarditis than right-sided endocarditis alone. *Staphylococcus aureus* is a more common etiologic microorganism in intravenous drug abusers than non-intravenous drug abusers and it is more likely to produce neurologic complications. Intravenous drug abusers

Figure 2.6.10 Coronal section of brain with multiple necrotic abscesses in an intravenous drug abuser.

can develop significant and life-threatening neurologic sequelae from toxins produced by *Clostridium tetani* and *botulinum* wound infections. Tetanus is commonly associated with subcutaneous injection or “skin popping.” Mexican “Black tar” heroin use was a risk factor in cases of botulism occurring in intravenous drug abusers during the mid-1990s. Nasal insufflation of drugs can also cause frontal sinusitis and overlying frontal lobe abscess.⁶⁹ Clostridia outbreaks reported from the United Kingdom involved mainly Iranian heroin.⁷⁰

2.6.9 Heroin Smokers Encephalopathy

Spongiform encephalopathy of obscure origin occurs in users of smoked drugs, but most cases have been in heroin abusers. An epidemic outbreak of spongiform leukoencephalopathy occurred in the Netherlands in 1982. It involved nearly 50 patients, many of whom died, none of whom fully recovered.⁷¹ The only factor common to all the individuals was that they all smoked heroin. All of the reported cases have had thorough toxicological investigation, but no agents have been identified. Sporadic cases have occurred over the last quarter century, mainly in Europe. A few of the victims have been cocaine users and several have been drug injectors. More recent magnetic resonance imaging (MRI) studies have shown diffuse white matter changes in all cases. Histologically there is widespread confluent vacuolar degeneration of the deep white matter, with evidence of severe, extensive, axonal injury.⁷² Various etiologies have been proposed including some unchar-

acterized defect in mitochondrial function or a direct toxic effect upon lipid-rich myelin. It may be that the disease has a latent period after the putative toxin is absorbed, but before symptoms appear. If so, that would explain the consistently negative toxicology testing results.

INTRODUCTION

Pharmacokinetics is defined as the study of the quantitative relationship between administered doses of a drug and the observed plasma/blood or tissue concentrations.¹ The pharmacokinetic model is a mathematical description of this relationship. Models provide estimates of certain parameters, such as elimination half-life, which provide information about basic drug properties. The models may be used to predict concentration vs. time profiles for different dosing patterns.

The field of pharmacokinetics is concerned with drug absorption, distribution, biotransformation, and excretion or elimination. These processes, in addition to the dose, determine the concentration of drug at the effector or active site and, therefore, the intensity and duration of drug effect. The practice of pharmacokinetics has been used in clinical medicine for many years in order to optimize the efficacy of medications administered to treat disease. Through a consideration of pharmacokinetics, physicians are able to determine the drug of choice, dose, route, and frequency of administration and duration of therapy, in order to achieve a specific therapeutic objective. In the same manner, study of the pharmacokinetics of abused drugs aids investigators in addiction medicine, forensic toxicology, and clinical pharmacology in understanding why particular drugs are abused, factors that affect their potential for abuse, how their use can be detected and monitored over time, and also provide a rational, scientific basis for treatment therapies.

3.1 BASIC CONCEPTS AND MODELS

3.1.1 Transfer across Biological Membranes

The processes of absorption, distribution, biotransformation, and elimination of a particular substance involve the transfer or movement of a drug across biological membranes. Therefore, it is important to understand those properties of cell membranes and the intrinsic properties of drugs that affect movement. Although drugs may gain entry into the body by passage through a single layer of cells, such as the intestinal epithelium, or through multiple layers of cells, such as the skin, the blood cell membrane is a common barrier to all drug entry and therefore is the most appropriate membrane for general discussion of cellular membrane structure. The cellular blood membrane consists of a phospholipid bilayer of 7- to 9-nm thickness with hydrocarbon chains oriented inward and polar head groups oriented outward. Interspersed between the lipid bilayer are proteins, which may span the entire width of the membrane permitting the formation of aqueous pores.² These

proteins act as receptors in chemical and electrical signaling pathways and also as specific targets for drug actions.³ The lipids in the cell membrane may move laterally, conferring fluidity at physiological temperatures and relative impermeability to highly polar molecules. The fluidity of plasma membranes is largely determined by the relative abundance of unsaturated fatty acids. Between cell membranes are pores that may permit bulk flow of substances. This is considered to be the main mechanism by which drugs cross the capillary endothelial membranes, except in the central nervous system (CNS), which possesses tight junctions that limit intercellular diffusion.³

Physicochemical properties of a drug also affect its movement across cell membranes. These include its molecular size and shape, solubility, degree of ionization, and relative lipid solubility of its ionized and non-ionized forms. Another factor to consider is the extent of protein binding to plasma and tissue components. Although such binding is reversible and usually rapid, only the free unbound form is considered capable of passing through biological membranes.

Drugs cross cell membranes through passive and active or specialized processes. Passive movement across biological membranes is the dominant process in the absorption and distribution of drugs. In passive transfer, hydrophobic molecules cross the cell membrane by simple diffusion along a concentration gradient. In this process there is no expenditure of cellular energy. The magnitude of drug transfer in this manner is dependent on the magnitude of the concentration gradient across the membrane and the lipid:water partition coefficient. Once steady state has been reached, the concentration of free (unbound) drug will be the same on both sides of the membrane. The exception to this situation is if the drug is capable of ionization under physiological conditions. In this case, concentrations on either side of the cell membrane will be influenced by pH differences across the membrane. Small hydrophilic molecules are thought to cross cell membranes through the aqueous pores.⁴ Generally, only unionized forms of a drug cross biological membranes due to their relatively high lipid solubility. The movement of ionized forms is dependent on the pKa of the drug and the pH gradient. The partitioning of weak acids and bases across pH gradients may be predicted by the Henderson–Hasselbalch equation. For example, an orally ingested weakly acidic drug may be largely unionized in the acidic environs of the stomach but ionized to some degree at the neutral pH of the plasma. The pH gradient and difference in the proportions of ionized/non-ionized forms of the drug promote the diffusion of the weak acid through the lipid barrier of the stomach into the plasma.

Water moves across cell membranes either by the simple diffusion described above or as the result of osmotic differences across membranes. In the latter case, when water moves in bulk through aqueous pores in cellular membranes due to osmotic forces, any molecule that is small enough to pass through the pores will also be transferred. This movement of solutes is called filtration. Cell membranes throughout the body possess pores of different sizes; for example, the pores in the kidney glomerulus are typically 70 nm, but the channels in most cells are <4 nm.²

The movement of some compounds across membranes cannot be explained by simple diffusion or filtration. These are usually high-molecular-weight or very lipid soluble substances. Therefore, specialized processes have been postulated to account for the movement. Active processes typically involve the expenditure of cellular energy to move molecules across biological membranes. Characteristics of active transport include selectivity, competitive inhibition, saturability, and movement across an electrochemical or concentration gradient. The drug complexes with a macromolecular carrier on one side of the membrane, traverses the membrane, and is released on the other side. The carrier then returns to the original surface. Active transport processes are important in the elimination of xenobiotics. They are involved in the movement of drugs in hepatocytes, renal tubular cells, and neuronal membranes. For example, the liver has four known active transport systems, two for organic acids, one for organic bases, and one for neutral organic compounds.² A different specialized transport process is termed “facilitated diffusion.” This transport is similar to the carrier-mediated transport described above except that no active processes are involved. The drug is not moved against an electrochemical or concentration gradient and there is no expenditure of energy. A biochemical example of such transport is the movement of glucose from the gastrointestinal tract through the intestinal epithelium.

3.1.1.1 Absorption

In order for a drug to exert its pharmacological effect, it must first gain entry into the body, be absorbed into the bloodstream, and transported or distributed to its site of action. This is true except in the case of drugs that exert their effect locally or at the absorption site. The absorption site, or port of entry, is determined by the route of drug administration.

Routes of administration are either enteral or parenteral. The former term denotes all routes pertaining to the alimentary canal. Therefore, sublingual, oral, and rectal are enteral routes of administration. All other routes, such as intravenous, intramuscular, subcutaneous, dermal, vaginal, and intraperitoneal, are parenteral routes.

Absorption describes the rate and extent to which a drug leaves its site of administration and enters the general circulation. Factors that, therefore, affect absorption include the physicochemical properties of the drug that determine transfer across cell membranes as described earlier; formulation or physical state of the drug; site of absorption; concentration of drug; circulation at absorption site; and area of absorbing surface.

Gastrointestinal

Absorption of drug may occur at any point along the tract including the mouth, stomach, intestine, and rectum. Because the majority of drugs are absorbed by passive diffusion, the non-ionized, lipid soluble form of the drug is favored for rapid action. Therefore, according to the Henderson–Hasselbalch equation, the absorption of weak acids should be favored in the stomach and the absorption of weak bases in the alkaline environment of the small intestine. However, other factors such as relative surface area will influence absorption. The stomach is lined by a relatively thick mucus-covered membrane to facilitate its primary function of digestion. In comparison, the epithelium of the small intestine is thin, with villi and microvilli providing a large surface area to facilitate its primary function of absorption of nutrients. Therefore, any factor that increases gastric emptying will tend to increase the rate of drug absorption, regardless of the ionization state of the drug.

The gastrointestinal (GI) tract possesses carrier-mediated transport systems for the transfer of nutrients and electrolytes across the gastric wall. These systems may also carry drugs and other xenobiotics into the organism. For example, lead is absorbed by the calcium transporter.⁵ Absorption also depends on the physical characteristics of a drug. For example, a highly lipid soluble drug will not dissolve in the stomach. In addition, solid dosage forms will have little contact with gastric mucosa and the drug will not be absorbed until the solid is dissolved. Further, the particle size affects absorption, since dissolution rate is proportional to particle size.⁶ Compounds that increase intestinal permeability or increase the residence time in the intestine by altering intestinal motility will thereby increase absorption of other drugs through that segment of the alimentary canal.

Once a drug has been absorbed through the GI tract, the amount of the compound that reaches the systemic circulation depends on several factors. The drug may be biotransformed by the GI cells or removed by the liver through which it must pass. This loss of drug before gaining access to the systemic circulation is known as the first pass effect.

Although oral ingestion is the most common route of GI absorption, drugs may be administered sublingually. Despite the small surface area for absorption, certain drugs which are non-ionic and highly lipid soluble are effectively absorbed by this route. The drugs nitroglycerin and buprenorphine are administered by this route. The blood supply in the mouth drains into the superior vena cava and, because of this anatomic characteristic, drugs are protected from first pass metabolism by the liver.

Although an uncommon route by which abused drugs are self-administered, rectal administration is used in medical practice when vomiting or other circumstances preclude oral administration. Approximately 50% of the drug that is absorbed will bypass the liver.³ The disadvantage of this

route for drug absorption is that the process is often incomplete and irregular and some drugs irritate the mucosal lining of the rectum.

Pulmonary

Gases, volatile liquids, and aerosols may be absorbed through the lungs. Access to the circulation by this route is rapid because of the large surface area of the lungs and extensive capillary network in close association with the alveoli. In the case of absorption of gases and volatilizable liquids, the ionization state and lipid solubility of the substance are less important than in GI absorption. This is because diffusion through cell membranes is not the rate-limiting step in the absorption process. The reasons include low volatility of ionized molecules, the extensive capillary network in close association with the alveoli resulting in a short distance for diffusion, and the rapid removal of absorbed substances by the blood. Some substances may not reach the lungs because they are deposited and absorbed in the mucosal lining of the nose.

Drugs may be atomized or volatilized and inhaled as droplets or particulates in air; a common example is the smoking of drugs. The advantages of this route include rapid transport into the blood, avoidance of first pass hepatic metabolism, and avoidance of the medical problems associated with other routes of illicit drug administration. Disadvantages include local irritant effect on the tissues of the nasopharynx and absorption of particulate matter in the nasopharynx and bronchial tree. For a drug to be effectively absorbed it should reach the alveoli. However, absorption of particulate matter is governed by particulate size and water solubility. Particles with diameters $>5\text{ }\mu\text{m}$ are usually deposited in the nasopharyngeal region;² particles in the 2- to $5\text{-}\mu\text{m}$ range are deposited in the tracheobronchiolar region and particles $1\text{ }\mu\text{m}$ and smaller reach the alveolar sacs.

Dermal

The skin is impermeable to most chemicals. For a drug to be absorbed it must pass first through the epidermal layers or specialized tissue such as hair follicles or sweat and sebaceous glands. Absorption through the outer layer of skin, the stratum corneum, is the rate-limiting step in the dermal absorption of drugs. This outer layer consists of densely packed keratinized cells and is commonly referred to as the “dead” layer of skin because the cells comprising this layer are without nuclei. Drug substances may be absorbed by simple diffusion through this layer. The lower layers of the epidermis, and the dermis, consist of porous nonselective cells that pose little barrier to absorption by passive diffusion. Once a chemical reaches this level, it is then rapidly absorbed into the systemic circulation because of the extensive network of venous and lymphatic capillaries located in the dermis. Drug absorption through the skin depends on the characteristics of the drug and on the condition of the skin. Since the stratum corneum is the main barrier to absorption, damage to this area by sloughing of cells due to abrasion or burning enhances absorption, as does any mechanism that increases cutaneous blood flow. Hydration of the stratum corneum also increases its permeability and therefore enhances absorption of chemicals.

Parenteral Injection

Drugs are often absorbed through the GI tract, lungs, and skin but many illicit drugs have historically been self-administered by injection. These routes typically include intravenous, intramuscular, and subcutaneous administration. The intravenous route of administration introduces the drug directly into the venous bloodstream, thereby eliminating the process of absorption altogether. Substances that are locally irritating may be administered intravenously since the blood vessel walls are relatively insensitive. This route permits the rapid introduction of the drug to the systemic circulation and allows high concentrations to be quickly achieved. Intravenous administration may result in unfavorable physiological responses because, once introduced, the drug cannot be removed.

This route of administration is dependent on maintaining patent veins and can result in extensive scar tissue formation due to chronic drug administration. Insoluble particulate matter deposited in the blood vessels is another medical problem associated with the intravenous route.

Intramuscular and subcutaneous administration involves absorption from the injection site into the circulation by passive diffusion. The rate of absorption is limited by the size of the capillary bed at the injection site and by the solubility of the drug in the interstitial fluid.³ If blood flow is increased at the administration site, absorption will be increased. Conversely, if blood pressure is decreased for any reason (such as cardiogenic shock) absorption will be prolonged.

3.1.1.2 Distribution

After entering circulation, drugs are distributed throughout the body. The extent of distribution is dependent on the physicochemical properties of the drug and physiological factors. Drugs cross cell membranes throughout the body by passive diffusion or specialized transport processes. Small water-soluble molecules and ions cross cell membranes through aqueous pores whereas lipid soluble substances diffuse through the membrane lipid bilayer. The rate of distribution of a drug is dependent on blood flow and the rate of diffusion across cell membranes of various tissues and organs. The affinity of a substance for certain tissues also affects the rate of distribution.

Because only unbound drug (the free fraction) is in equilibrium throughout the body, disposition is affected by binding to or dissolving in cellular constituents. While circulating in blood, drugs may be reversibly bound to several plasma proteins. For example, basic compounds often bind to α 1-acid glycoprotein; acidic compounds bind to albumin. The extent of plasma protein binding varies among drugs: nicotine is 5% bound whereas the barbiturate, secobarbital, is 50% bound, and the benzodiazepine, diazepam, is 96% bound.⁷ The fraction of drug that is bound is governed by the drug concentration, the drug's affinity for binding sites, and the number of binding sites available for binding. At low drug concentrations, the fraction bound is a function of the number of binding sites and the dissociation constant, a measure of binding affinity. When drug concentrations exceed the dissociation constant, concentration also governs the amount of protein binding. Therefore, published protein binding fractions for drugs only apply over a certain concentration range, usually the therapeutic concentration. Plasma protein binding limits the amount of drug entering tissues. Because plasma protein binding of drugs is relatively non-selective, drugs and endogenous substances compete for binding sites, and drug displacement from binding sites by another substance can contribute to toxicity by increasing the free fraction.

Binding to Tissue Constituents

In addition to binding to plasma proteins, drugs may bind to tissue constituents. The liver and kidney have a large capacity to act as storage depots for drugs. The mechanisms responsible for transfer of many drugs from the blood appear to be active transport processes.² Ligandin, a cytoplasmic liver protein, has a high affinity for many organic acids while metallothionein binds metals in the kidney and liver.

Lipid-soluble drugs are stored in neutral fat by dissolution. Since the fat content of an obese individual may be 50% body weight, it follows that large amounts of drug can be stored in this tissue. Once stored in fat, the concentration of drug is lowered throughout the body, in the blood and also in target organs. Any activity, such as dieting or starvation, which serves to mobilize fat, could potentially increase blood concentrations and hence contribute to an increase in the risk of drug toxicity.

Drugs may also be stored in bone. Drugs diffuse from the extracellular fluid through the hydration shell of the hydroxyapatite crystals of the bone mineral. Lead, fluoride, and other compounds may be deposited and stored in bone. Deposition may not necessarily be detrimental. For example, lead is not toxic to bone tissue. However, chronic fluoride deposition results in the

condition known as skeletal fluorosis. Generally, storage of compounds in bone is a reversible process. Toxicants may be released from the bone by ion exchange at the crystal surface or by dissolution of the bone during osteoclastic activity. If osteolytic activity is increased, the hydroxyapatite lattice is mobilized, resulting in an increase in blood concentrations of any stored xenobiotics.

Blood-Brain-Barrier

The blood-brain-barrier is often viewed as an impenetrable barrier to xenobiotics. However, this is not true and a more realistic representation is as a site that is less permeable to ionized substances and high-molecular-weight compounds than other membranes. Many toxicants do not enter the brain because the capillary endothelial cells are joined by tight junctions with few pores between cells; the capillaries of the CNS are surrounded by glial processes; and the interstitial fluid of the CNS has a low protein concentration. The first two anatomical processes limit the entry of small- to medium-sized water-soluble molecules, whereas the entry of lipid-soluble compounds is limited by the low protein content, which restricts paracellular transport. It is interesting to note that the permeability of the brain to toxicants varies from area to area. For example, the cortex, area postrema, and pineal body are more permeable than other regions.² This may be due to differences in blood supply or the nature of the barrier itself. Entrance of drugs into the brain is governed by the same factors that determine transfer across membranes in other parts of the body. Only the unbound fraction is available for transfer, and lipid solubility and the degree of ionization dictate the rate of entry of drugs into the brain. It should be noted that the blood-brain-barrier is not fully developed at birth. In animal studies, morphine has been found to be three to ten times more toxic to newborns than adults.⁸

Pregnancy

During pregnancy, drugs may also be distributed from the mother to the fetus by simple diffusion across the placenta. The placenta comprises several cell layers between the maternal and fetal circulations. The number of layers varies between species and state of gestation. The same factors govern placental drug transfer as movement by passive diffusion across other membranes. The placenta plays an additional role in preventing transfer of xenobiotics to the fetus by possessing biotransformation capabilities.

3.1.2 Biotransformation

Lipophilicity, a desirable drug characteristic for absorption and distribution across biological membranes, is a hindrance to elimination. To prevent accumulation of xenobiotics, the body chemically alters lipophilic compounds to more water soluble products. The sum of all the processes that convert lipophilic substances to more hydrophilic metabolites is termed biotransformation. These biochemical processes are usually enzymatic and are commonly divided into Phase I and Phase II reactions.⁹ Phase I reactions generally expose or introduce a polar group to the parent drug, thereby increasing its water solubility. These reactions are oxidative or hydrolytic in nature and include *N*- and *O*-dealkylation, aliphatic and aromatic hydroxylation, *N*- and *S*-oxidation, and deamination. These reactions usually result in loss of pharmacological activity, although there are numerous examples of enhanced activity. Indeed, formation of a Phase I product is desirable in the case of administration of prodrugs.

Phase II reactions are conjugation reactions and involve covalent bonding of functional groups with endogenous compounds. Highly water soluble conjugates are formed by combination of the drug or metabolite with glucuronic acid, sulfate, glutathione, amino acids, or acetate. Again, these products are generally pharmacologically inactive or less active than the parent compound. An exception is the metabolite morphine-6-glucuronide. In this case, glucuronidation at the 6-position

increases the affinity of morphine for binding at the mu receptor and results in equivalent or enhanced pharmacological activity.¹⁰

The enzymes that catalyze the biotransformation of drugs are found mainly in the liver. This is not surprising considering the primary function of the liver is to handle compounds absorbed from the GI tract. In addition, the liver receives all the blood perfusing the splanchnic area. Therefore, this organ has developed a high capacity to remove substances from blood, and store, transform, and/or release substances into the general circulation. In its primary role of biotransformation, the liver acts as a homogeneous unit, with all parenchymal cells or hepatocytes exhibiting enzymatic activity. In tissues involved in extrahepatic biotransformation processes, typically only one or two cell types are used. Many organs have demonstrated activity toward foreign compounds but the major extrahepatic tissues are those involved in the absorption or excretion of chemicals. These include the kidney, lung, intestine, skin, and testes. The main cells containing biotransformation enzymes in these organs are the proximal tubular cells, clara cells, mucosa lining cells, epithelial cells, and seminiferous tubules, respectively.

3.1.2.1 Phase I Enzymes

Phase I enzymes are located primarily in the endoplasmic reticulum of cells. These enzymes are membrane bound within a lipoprotein matrix and are referred to as microsomal enzymes. This is in reference to the subcellular fraction isolated by differential centrifugation of a liver homogenate. The two most important enzyme systems involved in Phase I biotransformation reactions are the cytochrome P450 system and the mixed function amine oxidase.

With the advances in recombinant DNA technology, eight major mammalian gene families of hepatic and extrahepatic cytochrome P450 have been identified.² A comprehensive discussion of the cytochrome P450 system is beyond the scope of this chapter and the reader is referred to a number of reviews.^{11–13} Briefly, this system comprises two coupled enzymes: NADPH-cytochrome P450 reductase and a heme containing enzyme, cytochrome P450. Numerous oxidative pathways for xenobiotics exist, both in humans and other animals. Much drug oxidation is performed by a group of enzymes known as CYPs (from *CY*tochrome *P450*, the 450 being derived from the cytochrome's maximal absorbance of light at 450 nm). The cytochrome P450s or CYPs are categorized according to amino acid sequence homology. CYPs that have less than 40% homology are placed in a different family (e.g., 1, 2, 3, and so on). CYPs that are 40 to 55% identical are assigned to different subfamilies (e.g., 1A, 1B, 1C, and so on). P450 enzymes that are more than 55% identical are classified as members of the same subfamily (e.g., 2B1, 2B2, 2B3). The P450 enzymes are expressed in numerous tissues, but are especially prevalent in the liver. For more information on this topic, see Chapter 5, which deals specifically with the subject of toxicogenetics. This complex is associated with another cytochrome, cytochrome b_5 with a reductase enzyme. In reactions catalyzed by cytochrome P450, the substrate combines with the oxidized form of cytochrome P450 (Fe^{3+}) to form a complex. This complex accepts an electron from NADPH, which reduces the iron in the cytochrome P450 heme moiety to Fe^{2+} . This reduced substrate–cytochrome P450 complex then combines with molecular oxygen, which in turn accepts another electron from NADPH. In some cases, the second electron is provided by NADH via cytochrome b_5 . Both electrons are transferred to molecular oxygen, resulting in a highly reactive and unstable species. One atom of the unstable oxygen molecule is transferred to the substrate and the other is reduced to water. The substrate then dissociates as a result, regenerating the oxidized form of cytochrome P450.

3.1.2.2 Phase II Enzymes

Many of the Phase II enzymes are located in the cytosol or supernatant fraction after differential centrifugation of a liver homogenate. These reactions are biosynthetic and therefore require energy.

This is accomplished by transforming the substrate or cofactors to high-energy intermediates. One of the major Phase II reactions is glucuronidation. The resultant glucuronides are eliminated in the bile or urine. The enzyme uridine diphosphate (UDP) glucuronosyltransferase is located in the endoplasmic reticulum. This enzyme catalyzes the reaction between UDP-glucuronic acid and the functional group of the substrate. The location of this enzyme means that it has direct access to the products of Phase I enzymatic reactions. Another important conjugation reaction in humans is sulfation of hydroxyl groups. The sulfotransferases are a group of soluble enzymes, classified as aryl, hydroxysteroid, estrone, and bile salt sulfotransferases. Their primary function is the transfer of inorganic sulfate to the hydroxyl moiety of phenol or aliphatic alcohols.

Another important family of enzymes is the glutathione-S-transferases, which are located in both the cytoplasm and endoplasmic reticulum of cells. The activity of the cytosolic transferase is 5 to 40 times greater than the endoplasmic enzyme. These transferase enzymes catalyze the reaction between the sulfhydryl group of the tripeptide glutathione with substances containing electrophilic carbon atoms. The glutathione conjugates are cleaved to cysteine derivatives, primarily in the kidney. These derivatives are then acetylated resulting in mercapturic acid conjugates, which are excreted in the urine.

Many factors affect the rate at which a drug is biotransformed. One of the important factors is obviously the concentration of the drug at the site of action of biotransforming enzymes. Physicochemical properties of the drug, such as lipophilicity, are important, in addition to dose and route of administration. Certain physiological, pharmacological, and environmental factors may also affect the rate of biotransformation of a compound. Numerous variables affect biotransformation including sex, age, genetic polymorphisms, time of day or circadian rhythms, nutritional status, enzyme induction or inhibition, hepatic injury, and disease states.

3.1.3 Elimination

Drugs are excreted or eliminated from the body as parent compounds or metabolites. The organs involved in excretion, with the exception of the lungs, eliminate water-soluble compounds more readily than lipophilic substances. The lungs are important for the elimination of anesthetic gases and vapors. The processes of biotransformation generally produce more polar compounds for excretion. The most important excretory organ is the kidney. Substances in the feces are mainly unabsorbed drugs administered orally or compounds excreted into the bile and not reabsorbed. Drugs may also be excreted in breast milk¹⁴ and, even though the amounts are small, they represent an important pathway because the recipient of any drugs by this route is the nursing infant.

For a comprehensive discussion of renal excretion of drugs, the reader is referred to Weiner and Mudge.¹⁵ Excretion of drugs and their metabolites involves three processes, namely, glomerular filtration, passive tubular reabsorption, and active tubular secretion. The amount of a drug that enters the tubular lumen of the kidney is dependent on the glomerular filtration rate and the fraction of drug that is plasma protein bound. In the proximal renal tubular organic anions and cations are added to the filtrate by active transport processes. Glucuronide drug metabolites are secreted in this way by the carrier-mediated system for naturally occurring organic acids. In the proximal and distal tubules of the kidney, the non-ionized forms of weak acids and bases are passively reabsorbed. The necessary concentration gradient is created by the reabsorption of water with sodium. The passive reabsorption of ionized forms is pH dependent because the tubular cells are less permeable to these moieties. Therefore, in the treatment of drug poisoning, the excretion of some drugs can be increased by alkalization or acidification of the urine.

Under normal physiological conditions, excretion of drugs in the sweat, saliva, and by the lacrimal glands is quantitatively insignificant. Elimination by these routes is dependent on pH and diffusion of the unionized lipid-soluble form of the drug through the epithelial cells of the glands. Drugs excreted in saliva enter the mouth and may be reabsorbed and swallowed. Drugs have also

been detected in hair and skin, and although quantitatively unimportant, these routes may be useful in drug detection and therefore have forensic significance.

3.1.4 Pharmacokinetic Parameters

Pharmacokinetics assumes that a relationship exists between the concentration of drug in an accessible site, such as the blood, and the pharmacological or toxic response. The concentration of drug in the systemic circulation is related to the concentration of drug at the site of action. Pharmacokinetics attempts to quantify the relationship between dose and drug disposition and provide the framework, through modeling, to interpret measured concentrations in biological fluids.³ Several pharmacokinetic parameters are utilized to explain various pharmacokinetic processes. It is often changes in these parameters, through disease, genetic abnormalities, or drug interactions, that necessitate modifications of dosage regimens for therapeutic agents. The most important parameters are clearance, the ability of the body to eliminate drug, volume of distribution, a measure of the apparent volume of the body available to occupy the drug, bioavailability, the proportion of drug absorbed into the systemic circulation, and half-life, a measure of the rate of drug elimination from the blood. These concepts are discussed below.

3.1.4.1 Clearance

Clearance is defined as the proportionality factor that relates the rate of drug elimination to the blood or plasma drug concentration:¹⁶

$$\text{Clearance} = \text{Rate of elimination} / \text{Concentration}$$

In the above equation, the concentration term refers to drug concentration at steady state. The units of clearance are volume per unit time and, therefore, this parameter measures the volume of biological fluid, such as blood, that would have to have drug removed to account for drug elimination. Therefore, clearance is not a measure of the amount of drug removed.

The concept of clearance is useful in pharmacokinetics because clearance is usually constant over a wide range of concentrations, provided that elimination processes are not saturated. Saturation of biotransformation and excretory processes may occur in overdose and toxicokinetic effects should be considered. If a constant fraction of drug is eliminated per unit time, the elimination follows first-order kinetics. However, if a constant amount of drug is eliminated per unit time, the elimination is described by zero-order kinetics. Some drugs, for example, ethanol, exhibit zero-order kinetics at “normal” or non-intoxicating concentrations. However, for any drug that exhibits first-order kinetics at therapeutic or nontoxic concentrations, once the mechanisms for elimination become saturated, the kinetics become zero order and clearance becomes variable.³

Clearance may also be viewed as the loss of drug from an organ of elimination such as the liver or kidney. This approach enables evaluation of the effects of a variety of physiological factors such as changes in blood flow, plasma protein binding, and enzyme activity. Therefore, total systemic clearance is determined by adding the clearance (CL) values for each elimination organ or tissue:

$$CL_{\text{systemic}} = CL_{\text{renal}} + CL_{\text{hepatic}} + CL_{\text{lung}} + CL_{\text{other}}$$

Clearance from an individual organ is a product of blood flow and the extraction ratio. The extraction ratio is derived from the concentration of drug in the blood entering the organ and the concentration of drug in the blood leaving the organ. If the extraction ratio is 0, no drug is removed. If it is 1, then all the drug entering the organ is removed from the blood. Therefore, the clearance of an organ may be determined from the following equation:

$$CL_{\text{organ}} = Q(C_A - C_V/C_A) = Q \times E$$

where

Q = blood flow

C_A = arterial drug concentration

C_V = venous drug concentration

E = extraction ratio

3.1.4.2 Volume of Distribution

The plasma drug concentration reached after distribution is complete is a result of the dose and the extent of uptake by tissues. The extent of distribution can be described by relating the amount of drug in the body to the concentration. This parameter is known as the volume of distribution. This volume does not indicate a defined physiological dimension but the volume of fluid required to contain all the drug in the body at the same concentration as in the plasma or blood. Therefore, it is often called the apparent volume of distribution (V) and is determined at steady state when distribution equilibrium has been reached between drug in plasma and tissues.

$$V = \text{Amount in body} / \text{Plasma drug concentration}$$

The volume of distribution depends on the pKa of the drug, the degree of plasma protein and tissue binding, and the lipophilicity of the drug. As would be expected, drugs that distribute widely throughout the body have large volumes of distribution (for example, the V_d of fluphenazine, which is a widely distributed drug, is 11; the V_d for ketoconazole is only 0.7, indicating that very little drug leaves the circulation). In the equation above, the body is considered one homogeneous unit and therefore exhibits a one-compartment model. In this model, drug administration occurs in the central compartment, and distribution is instantaneous throughout the body. For most drugs, the simple one-compartment model does not describe the time course of drug in the body adequately and drug distribution and elimination is more completely described in multiple exponential terms using multicompartmental models. In these models, the volume of distribution, V_{area} , is calculated as the ratio of clearance to the rate of decline of the concentration during the elimination phase:

$$V_{\text{area}} = CL/k$$

where k = rate constant.

3.1.4.3 Bioavailability

The bioavailability of a drug refers to the fraction of the dose that reaches the systemic circulation. This parameter is dependent on the rate and extent of absorption at the site of drug administration. Obviously, it follows that drugs administered intravenously do not undergo absorption, but immediately gain access to the systemic circulation and are considered 100% bioavailable. In the case of oral administration, if the hepatic extraction ratio is known, it is possible to predict the maximum bioavailability of drug by this route assuming first-order processes, according to the following equation:³

$$F_{\text{max}} = 1 - E = 1 - (CL_{\text{hepatic}}/Q_{\text{hepatic}})$$

The bioavailability of a drug by various routes may also be determined by comparing the area under the curve (AUC) obtained from the plasma concentration vs. time curve after intravenous and other routes of administration:⁹

$$\text{Bioavailability} = \text{AUC}_{\text{oral}}/\text{AUC}_{\text{IV}}$$

3.1.4.4 Half-Life

The half-life is the time it takes for the plasma drug concentration to decrease by 50%. Half-life is usually determined from the log-terminal phase of the elimination curve. However, it is important to remember that this parameter is a derived term and is dependent on the clearance and volume of distribution of the drug. Therefore, as CL and V change with disease, drug interactions, and age, so a change in the half-life should be expected. The half-life is typically calculated from the following equation:

$$t_{1/2} = 0.693/k$$

where $t_{1/2}$ = half life and k = elimination rate constant.

Because $k = \text{CL}/V$, the interrelationship between these parameters is clearly evident.

3.1.5 Dosage Regimens

Pharmacokinetic principles, in addition to clinical factors such as the state of the patient, are utilized in determining dosage regimens. Factors that relate to the safety and efficacy of the drug such as activity–toxicity relationships (therapeutic window and side effects), and pharmaceutical factors, such as dosage form and route of administration, must be considered.¹⁶

The goal of a therapeutic regimen is to achieve therapeutic concentrations of a drug continuously or intermittently. The latter is useful if tolerance to the drug develops, or if the therapeutic effects of the drug persist and increase in intensity even with rapid drug disappearance. Adjustments to the dosage regimen are made to maintain therapeutically effective drug concentrations and minimize undesirable effects. Optimization of drug therapy is typically determined empirically, that is, changing the dose based on response of the individual. However, there is often better correlation between blood or plasma concentration or amount of drug in the body than the dose administered. Therefore, pharmacokinetic data are useful in the design of dosage regimens. In theory, data following a single dose may be used to estimate plasma concentrations following any dosing design.

For drugs whose effects are difficult to measure, or whose therapeutic index is low, a target-level or steady-state plasma concentration is desirable. A dose is computed to achieve this level, drug concentrations are measured, and the dose is adjusted accordingly. To apply this strategy, the therapeutic range should be determined. For many drugs the lower limit of this range appears to be the concentration that produces 50% maximal response. The upper limit is determined by drug toxicity and is commonly determined by the concentration at which 5 to 10% of patients experience a toxic effect.³ The target concentration is then chosen at the middle of the therapeutic range.

3.1.5.1 Loading Doses

The loading dose is one or a series of doses that are administered at the beginning of therapy. The objective is to reach the target concentration rapidly. The loading dose can be estimated using the following formula:

$$\text{Loading Dose} = \text{Target } C_p \times V_{ss}/F$$

where C_p = concentration in plasma, V_{ss} = volume of distribution at steady state, and F = fractional bioavailability of the dose.

A loading dose is desirable if the time to achieve steady state is long compared to the need for the condition being treated. One disadvantage of a loading dose is the acute exposure to high concentrations of the drug, which may result in toxic effects in sensitive individuals.

3.1.5.2 Dosing Rate

In the majority of clinical situations, drugs are administered as a series of repeated doses or as a continuous infusion in order to maintain a steady-state concentration. Therefore, a maintenance dose must be calculated such that the rate of input is equal to the rate of drug loss. This may be determined using the following formula:

$$\text{Dosing Rate} = \text{Target} \times \text{CL}/F$$

where CL = clearance and F = fractional bioavailability of the dose.

It is obvious from the above that in order to design an appropriate dosage regimen, several pharmacokinetic factors, including CL, F , V_{ss} , and half-life, must be known in addition to an understanding of the principles of absorption and distribution of the drug in question. The clinician must also be aware of variations in these factors in a particular patient. One should note that even “normal” individuals exhibit variations in these parameters. For example, one standard deviation on clearance values may be 50%. These unpredicted variations in pharmacokinetic parameters may result in a wide range of drug concentrations. This is unacceptable in most cases especially for those drugs with a low therapeutic index. Therefore, C_p should be measured and estimates of CL, F , and V_{ss} calculated directly.

3.1.6 Therapeutic Drug Monitoring

Blood or plasma drug concentrations at steady state are typically measured to refine estimates of CL/ F for the individual. Updated estimates are then used to adjust maintenance doses to reach the desired target concentration. Drug concentrations can be misleading if the relevant pharmacokinetics (and toxicokinetics; see Section 3.4) are not considered. In addition, individual variability in drug response, due to multiple drug use, disease, genetic differences, and tolerance, must be considered. Pharmacokinetic characteristics of drugs may differ with development and age. Therefore, drug effects may vary considerably between infants, children, and adults. For example, water constitutes 80% of the weight of a newborn whereas in adults it constitutes approximately 60%. These differences affect distribution of drugs throughout the body.

3.1.6.1 Plasma

Measurement of drug concentrations in plasma is the cornerstone of therapeutic drug monitoring (TDM), but it is not without pitfalls. In many instances, clinical response does not correlate with plasma drug concentrations. Other considerations may be as follows.

Time Delays

It often takes time for a response to reflect a given plasma concentration due to the individual kinetics of the drug. Until this equilibrium is reached, correlation between response and concentration is difficult and may lead to misinterpretation of the clinical picture. Delay may be due to lack of equilibration between plasma and target organ as the drug distributes throughout the body. In addition, delay may be because the response measured is an indirect measure of drug effect,

e.g., a change in blood pressure is an indirect measure of either change in peripheral resistance or cardiac output or both.

Active Metabolites

Poor correlation may be found between response and plasma concentration of parent drug if active metabolites are present and not measured. Formation of active metabolites may be a function of the route of drug administration because oral ingestion generally produces an initial surge of metabolites due to the first-pass effect of the liver compared with drugs administered intravenously.

Exposure Duration

Some drugs exhibit unusual concentration/response relationships, which minimizes the utility of TDM. In these cases, clinical response correlates more with duration of dosing than the actual dose or resultant plasma concentrations.

Tolerance

The effectiveness of a drug may diminish with continual use. Tolerance denotes a decreased pharmacological responsiveness to a drug. This is demonstrated by several drugs of abuse including ethanol and heroin. The degree of tolerance varies but is never complete. For example, tolerance to the effects of morphine quickly develops, but the user is not totally unresponsive to the pharmacological effects. To compensate for the development of tolerance, the dose is increased. Tolerance may develop slowly, such as in the case of tolerance to the CNS effects of ethanol, or can occur acutely (tachyphylaxis) as in the case of nicotine. In these cases, a correlation may be found between plasma drug concentration and the intensity of response at a given moment, but the relationship is not consistent and varies with time.¹⁶

3.1.6.2 Saliva

In recent years, saliva has been utilized for TDM. The advantage is that collection is noninvasive and painless and so it has been used as a specimen of choice in pediatric TDM. Due to the low protein content of saliva, it is considered to represent the unbound or free fraction of drug in plasma. Since this is the fraction considered available for transfer across membranes and therefore responsible for pharmacological activity, its usefulness is easy to understand. Saliva collection methods are known to influence drug concentrations, but if these are compensated for and a standardized procedure utilized, correlation between plasma and saliva drug concentrations may be demonstrated for several drugs (e.g., phenytoin). Inconsistent results have been found for some drugs such as phenobarbital, so additional studies are needed to clearly define the limitations of testing saliva for TDM.

3.2 PHARMACOKINETIC MODELING

3.2.1 Compartmental Modeling

The pharmacokinetic profile of a drug is described by the processes of absorption, distribution, metabolism, and excretion. The disposition of a drug in the body may be further delineated by mathematical modeling. These models are based on the concept that the body may be viewed as a series of compartments in which the drug is distributed. If the compartmental concept is considered

literally, then each tissue and organ becomes an individual compartment. However, in pharmacokinetic modeling, several organs or tissues exhibit similar characteristics in drug deposition and are often considered the same compartment. The pharmacokinetic profiles of many drugs may be explained using one- or two-compartment models, but more complex models exist and, with the advances in computer software, the ability to describe drug disposition has increased. The use of models does not mean that the drug distributes into distinct physiological compartments, but that these mathematical models adequately describe the fate of the drug in the human body.

3.2.1.1 One-Compartment Models

In the one-compartment model the entire body is considered as one unit (Figure 3.2.1A). The drug is administered into the compartment and distributed throughout the compartment (the body) instantaneously.¹⁷ Similarly, the drug is eliminated directly from the one compartment at a rate measured by k_{el} , the elimination rate constant. The time course of the drug, as measured in the readily accessible blood or plasma, is typically graphed as a log concentration vs. time profile. Figure 3.2.1B shows the log plasma concentration vs. time plot for a drug that distributes according to a one-compartment model. The dotted line demonstrates the time course after intravenous administration and the solid line demonstrates the time course after oral administration. Since intravenous administration does not have an absorption phase, the time course of drug in the plasma is linear. For oral administration, the drug concentration on the blood is slower to reach a peak due to absorptive processes of the GI tract.

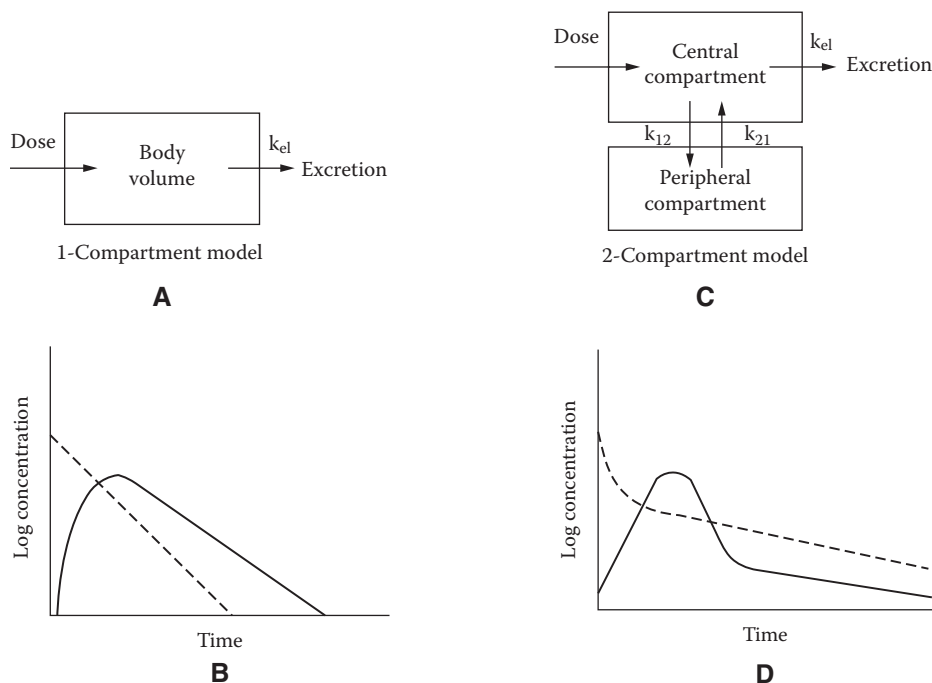

Figure 3.2.1 (A) Schematic representation of a one-compartment model. (B) Log plasma concentration vs. time curve after intravenous (---) and oral (-) administration. (C) Schematic representation of a two-compartment model. (D) Log plasma concentration vs. time curve after intravenous (---) and oral (-) administration. (Adapted from Hagan, R.L., Basic Pharmacokinetics. In-Service Training and Continuing Education AACC/TDM, American Association for Clinical Chemistry, Inc., Washington, D.C., 17(9), 231–247, 1996.)

3.2.1.2 Two-Compartment Models

Figure 3.2.1C illustrates the concept of the two-compartment model. In this model, the drug is administered into the central compartment and then there is a time lag due to slower distribution into other tissues and organs. These other organs are represented by the peripheral compartment(s). More complex models may be developed if distribution to other organs occurs at different rates that can be mathematically differentiated. In the two-compartment model, equilibrium is reached between the central and peripheral compartments and this marks the end of the distribution phase. The beginning of the distribution phase may be observed graphically by an initial rapid decline after peaking in the drug concentration in the central compartment (represented by the plasma/blood) as shown in Figure 3.2.1D. Rate constants may be estimated for drug movement between the central and peripheral compartments, but drug elimination from the body is assumed to occur from the central compartment.¹⁷ As mentioned previously, more complex models may be developed including models in which the number of compartments into which the drug distributes is not assumed in the initial modeling.

3.2.1.3 Elimination Kinetics

The concept of zero- or first-order kinetics may be utilized to describe any rate process in pharmacokinetics. Therefore, if we are discussing drug absorption, a drug exhibits zero-order kinetics if a constant amount of drug is absorbed regardless of dose.⁹ Conversely, a drug exhibits first-order absorption kinetics if the amount absorbed is dependent on dose, i.e., is a fraction of the dose. Similarly, when considering drug excretion, ethanol exhibits zero-order elimination kinetics because a constant amount of drug is excreted per unit time regardless of the drug concentration (unless processes become saturated). Most drugs exhibit first-order elimination kinetics in which a constant fraction of drug is eliminated per unit time.

Zero-order elimination kinetics are described by the following equation:¹⁷

$$C = C_0 - kt$$

where C = drug concentration at time t , C_0 = the concentration at time zero or the initial concentration, and k = the elimination rate constant.

A plot of this equation is linear with a slope, $-k$, and a y-intercept, C_0 . The elimination half-life may be calculated from this equation for a drug that exhibits zero-order elimination. When $t = t_{1/2}$, then $C = 1/2 C_0$, the initial or peak concentration. This results in the following equation:

$$t_{1/2} = 1/2 C_0/k$$

This equation has a concentration term, C_0 , indicating that the half-life is variable and dependent on drug concentration. Changes in pharmacokinetic parameters that occur as a function of dose or drug concentration are referred to as nonlinear pharmacokinetic processes. Nonlinearity is usually due to saturation of protein binding, hepatic metabolism, or active renal transport of the drug.³

First-order elimination kinetics are described by the equation:¹⁷

$$C = C_0 e^{-kt}$$

Taking the natural logarithm of this equation and plotting it semilogarithmically results in a linear graph with a slope of $-k$, and a y-intercept of $\ln C_0$. Again, to determine the half-life, $1/2 C_0$ is substituted into the equation to give:

$$1/2 C_0 = C_0 e^{-kt_{1/2}}$$

Taking natural logs and solving for $t_{1/2}$:

$$t_{1/2} = 0.693/k$$

It is important to note that the elimination half-life is a derived term, and any process that changes k will change the half-life of the drug. Factors that may affect pharmacokinetic parameters are discussed elsewhere, but in this example may include disease states, changes in urinary pH, changes in plasma protein binding, and coadministration of other drugs.

3.2.2 Physiological Models

An alternative method of building a pharmacokinetic profile of a drug in the body is to utilize anatomic and physiological information. Such a model does not make assumptions about body compartments or first-order processes for drug absorption and elimination.¹⁶ The first step in such modeling is to decide whether drug distribution into a particular tissue is perfusion rate or membrane transport limited.² These decisions are based on the physicochemical characteristics of the drug and physiological conditions in addition to reference to any experimental data. In order to write a mass balance equation, blood flow, Q , and the volume, V , of the organ or tissue of interest is needed and may be obtained from the literature. The other parameters, venous drug concentration, C_v , and the partition coefficient, R , are determined experimentally.² A simple mass balance equation may be written as:²

$$V_t \times dC_t/dt = Q_t \times [C_v - C_t/R_t]$$

where t = tissue.

Mass balance equations may be constructed for each organ or tissue considered and algebraic equations added to account for growth, changes in tissue weight ratios, and other physiological parameters. The advantage of this modeling over the more traditional compartmental method is provision of a time course of drug distribution to any organ or tissue, and this model allows estimation of the effects of changing physiological parameters on tissue concentrations. Disadvantages include the need for complex mathematical equations and the lack of data on the physiological parameters necessary to construct the differential equations.²

3.3 PHARMACOKINETIC–PHARMACODYNAMIC CORRELATIONS

Pharmacodynamics (PD) may be defined as the quantitative relationship between the measured plasma or tissue concentration of the active moiety and the magnitude of the observed pharmacological effect(s).¹ The study of pharmacokinetics (PK) has been defined previously. A PK/PD model is a mathematical description of the relationship. Knowledge of the model and model parameter estimates permits prediction of concentration vs. time and effect vs. time profiles for different dosing regimens.¹ Different drugs are characterized by different PK and PD models and by differences in model parameters such as volume of distribution and receptor affinity. Understanding the PK/PD model permits comparison of the pharmacological properties for different drugs. For a specific compound, there may be significant variation in model parameters between individuals. PK/PD modeling allows assessment of the contribution of the variability in model parameters to the overall variability in drug response.¹

To fully understand the significance of PK/PD modeling, it is important to note that the observed effect vs. time profile for a particular individual is determined by several factors. These include (1) drug input dose, rate, and route of administration; (2) intrinsic PK drug properties; and (3) intrinsic PD drug properties. Modeling allows estimation of PK/PD parameters. Further, PK/PD modeling provides dose–response curves for the onset, magnitude, and duration of effects that can be utilized to optimize dose and dosing regimens. Models have been described for reversible and irreversible drug effects and for a range of drug classes including analgesics, benzodiazepines, and anticonvulsants. For a more detailed explanation of PK/PD modeling and correlations and description of computer applications, the reader is referred elsewhere.¹

3.4 TOXICOKINETICS

Toxicokinetics is the study of drug disposition in overdose. The biochemical processes that constitute the science of pharmacokinetics may be altered when drugs are administered in high concentrations. GI absorption may be altered in overdose due to delayed gastric emptying, changes in intestinal motility, and therapy with activated charcoal.² Drugs such as morphine, ethanol, and barbiturates delay gastric emptying and as a consequence slow drug movement into the small intestine. In addition, morphine decreases intestinal motility, resulting in increased transit time through the intestine and increased absorption. Little is known about changes in drug distribution throughout the body after overdose. Several mechanisms may be at work in overdose to cause changes in drug disposition. For example, the bioavailability of a drug with a high first pass metabolism may be increased when the hepatic metabolizing enzymes become saturated. In a similar manner, the concentration of free drug in the plasma may be increased when protein binding becomes saturated. This may result in significant toxicity for those drugs that are highly plasma protein bound. Also, changes in peripheral blood flow due to the cardiac effects of some drugs may result in prolonged drug distribution and higher blood drug concentrations.

Drug metabolism may be altered in overdose when those enzymes responsible for metabolism become saturated. In this event, clearance is decreased, half-life is prolonged, and therefore high drug concentrations exist for a longer time. If multiple drugs are co-ingested, competitive inhibition of metabolism may occur. In addition, if hepatic blood flow is decreased, due to impaired liver function or cardiovascular drug effects, biotransformation of xenobiotics may be decreased.

Renal excretion may or may not be altered in drug overdose. Alteration of renal drug clearance may be utilized therapeutically to enhance drug elimination. Urinary pH is adjusted to increase the clearance of acidic and basic drugs. For example, administration of sodium bicarbonate will raise the urine pH above 7.5, concentrating the ionized form in the renal tubule and, therefore, enhancing elimination of salicylate. Conversely, acidification of the urine may be utilized to enhance renal excretion of basic drugs. However, with some drugs, such as phencyclidine, there is controversy about the role of urinary acidification in enhanced excretion and whether this procedure improves clinical outcome. Acidification is contraindicated with myoglobinuria and may also increase the risk of metabolic complications.¹⁸

3.5 FACTORS AFFECTING PHARMACOKINETIC PARAMETERS

Toxicokinetics is utilized to describe the changes in pharmacokinetic processes as a result of drug overdose. Other factors may contribute to changes in pharmacokinetic parameters when nontoxic doses are therapeutically or illicitly administered. Besides species differences in the variability in drug response, which are not discussed here, other factors that contribute to changes

in parameters include drug formulation and route of administration, gender differences, age, weight or body composition, disease, genetic abnormalities, and drug interactions.

3.5.1 Genetic Factors

When a distinguishable difference between individuals is under genetic control, it is known as genetic polymorphism. Some drug responses have been found to be genetically determined. For example, the activity of the liver enzyme *N*-acetyltransferase differs between individuals such that the population may be divided into slow and fast acetylators. Approximately 60% of the U.S. population are slow acetylators and may show toxicity unless doses of drugs requiring acetylation for metabolism are reduced. Other inherited variations in pharmacokinetics include deficiency of one or more hepatic cytochrome-P450 isozymes or plasma cholinesterase.²

3.5.2 Sex Differences

Examples of sex differences in drug pharmacokinetics have also been identified. These differences may be due to variations in body composition, hepatic metabolism, renal elimination, protein binding, or absorption. Differences in weight may influence muscle mass, organ blood flow, body water spaces, and hence affect the pharmacokinetic parameters of many drugs. In addition, women tend to have a higher percentage of body fat than men, which will affect the volume of distribution of lipophilic drugs. The clinical significance of differences in body composition is unclear but there are some important examples: women have a lower volume of distribution (*V*) of ethanol¹⁹ and a higher *V* for diazepam than men.

A number of studies have examined the effect of gender on hepatic metabolism and drug elimination. Greenblatt et al.²⁰ found that young women have a significantly higher CL for diazepam than young men. In contrast, clearances of oxazepam²¹ and chlordiazepoxide²² are higher in men than in women and no sex difference has been observed in the metabolism of nitrazepam or lorazepam.¹⁹ Differences can be explained by differences in metabolic pathways because oxazepam is metabolized primarily through conjugation, nitrazepam is metabolized by reduction of the nitro group, and most of the other benzodiazepines are metabolized by various cytochrome P450 isozymes. It has been found that the isozyme cytochrome 3A4, responsible for the metabolism of many drugs, is approximately 1.4 times more active in women than men. The isozymes P2D6 and P2C19 display genetic polymorphism that is not influenced by gender. The isozyme P1A2 may be influenced by sex although the data are inconclusive. The work of Relling et al.²³ suggests that the activity of this isozyme is lower in women than men. As mentioned above, gender differences have been demonstrated in the elimination of drugs that are metabolized solely by conjugation. The male:female clearance ratio for oxazepam is approximately 1.5:1.

When considering renal elimination, the glomerular filtration rate (GFR) is on average higher in men than women,¹⁹ but this may be a weight rather than a gender effect as GFR is directly proportional to weight. The effects of gender on tubular secretion and reabsorption have not been well characterized. The influence of gender on plasma protein binding appears to be minimal. Albumin levels are not altered by gender in contrast to the protein α 1-acid glycoprotein, which is reduced by estrogen.²⁴ Other plasma constituents whose levels are influenced by gender include cortico-steroid binding globulin and various lipoproteins.²⁵ Gender differences in the binding of diazepam and chlordiazepoxide have been demonstrated.

Some studies have suggested that gender influences gastric emptying rate and intestinal transit time.²⁶ Women empty solids from the stomach more slowly than men and the activity of a stomach enzyme, alcohol dehydrogenase, may be much lower in women. The GI tract also contains large concentrations of the isozyme cytochrome P3A4, so gender differences in the activity of this enzyme could affect the bioavailability of certain drugs. Gender differences observed after intramuscular drug administration may be due to differences in blood flow or incorrect injection into fat in women.

Drug absorption in the lung may differ according to gender. Knight et al.²⁷ found significantly less deposition of an aerosolized drug in women than men, which the authors attributed to differences in breathing characteristics.

It should be noted that female-specific issues may have significant effects on drug distribution and metabolism. For example, pregnancy may increase the elimination of certain drugs, reducing their efficacy. In addition, oral contraceptive use can affect the metabolism of drugs. The effects of menopause, menstruation, and hormone replacement on the pharmacokinetics of drugs are largely unknown.

3.5.3 Age

Changes in the rate but not the extent of drug absorption are usually observed with age.¹⁶ Factors that affect drug absorption, such as gastric pH and emptying, intestinal motility, and blood flow, change with age. Gastric acid secretion does not approach adult levels until the age of 3 and gastric emptying and peristalsis is slow during the first few months of life. Because skeletal muscle mass is limited, muscle contractions, which aid blood flow, are minimal, and therefore will limit the distribution of intramuscularly administered drug. Higher gastric pH, delayed gastric emptying, and decreased intestinal motility and blood flow are observed in elderly individuals.

3.5.4 Drug and Disease Interactions

The pharmacokinetics of several drugs have been shown to be influenced by concurrent disease processes.¹⁶ The clearance of many drugs decreases in those individuals with chronic hepatic disease such as cirrhosis. In contrast, in acute reversible liver conditions, such as acute viral hepatitis, the clearance of some drugs is decreased or the half-life increased and, for others, no change is detected. The volumes of distribution of some drugs are unaltered in hepatic disease while an increase is observed for other drugs, especially those bound to albumin in individuals with cirrhosis. This phenomenon is due to the decreased synthesis of albumin and other proteins. The influence of liver disease on drug absorption is unclear. It is probable, however, that the oral bioavailability of drugs highly extracted from the liver is increased in cirrhosis. The reasons are decreased first pass hepatic metabolism and the development of portal bypass in which blood enters the superior vena cava directly via esophageal varices.

Renal diseases such as uremia may result in decreased renal clearance of certain drugs.¹⁶ Gastrointestinal diseases, such as Crohn's disease, result in increased plasma protein binding of several drugs due to increased levels of binding proteins. Further, respiratory diseases such as cystic fibrosis increase the renal clearance of some drugs.

Patients commonly receive two or more drugs concurrently and most individuals who abuse drugs are polydrug users. Multiple drug use may result in drug interactions. This occurs when the pharmacokinetics or pharmacodynamics of one drug is altered by another. This concept is important to consider because interaction may result in decreased therapeutic efficacy or an increased risk of toxicity. The degree of drug interaction depends on the relative concentrations and therefore dose and time.¹⁶ Changes in absorption rate, competition for binding sites on plasma proteins, oral bioavailability, volume of distribution, and hepatic and renal clearance have been demonstrated for therapeutic drugs. Few studies have systematically documented pharmacokinetic interactions between illicit drugs.

3.6 PHARMACOKINETICS OF SPECIFIC DRUGS

3.6.1 Amphetamine

The term *amphetamine* refers to the group of stimulants that includes amphetamine, methamphetamine, methylenedioxyamphetamine, and methylenedioxymethamphetamine. These low-molecular-weight basic drugs are sympathomimetic phenethylamine derivatives possessing central and peripheral stimulant activity. Amphetamines suppress appetite and produce CNS and cardiovascular stimulation. These effects are mediated by increasing synaptic concentrations of norepinephrine and dopamine either by stimulating neurotransmitter release or inhibiting uptake, or both. Clinical uses of amphetamine and methamphetamine include chronic administration for the treatment of narcolepsy in adults and attention-deficit/hyperactivity disorder in children.¹

These drugs are abused for their stimulant effect. The effects are usually longer lasting than those of cocaine and may prevent fatigue. The latter factor has led to their study in athletes and in military field situations. It is postulated that the disturbances in perception and psychotic behavior, which may occur at high doses, may be due to dopamine release from dopaminergic neurons and also serotonin release from tryptaminergic neurons located in the mesolimbic area of the brain.

Amphetamine and methamphetamine occur as structural isomers and stereoisomers. Structural isomers are compounds with the same empirical formula but a different atomic arrangement, e.g., methamphetamine and phentermine. Stereoisomers differ in the three-dimensional arrangement of the atoms attached to at least one asymmetric carbon and are nonsuperimposable mirror images. Therefore, amphetamine and methamphetamine occur as both D- and L- isomeric forms. The two isomers together form a racemic mixture. The D-amphetamine form has significant stimulant activity, and possesses approximately three to four times the central activity of the L-form. It is also important to note that the D- and L-enantiomers may have not only different pharmacological activity but also varying pharmacokinetic characteristics.

When indicated for therapeutic use, 5 to 60 mg or 5 to 20 mg of amphetamine or methamphetamine, respectively, are administered orally. An oral dose of amphetamine typically results in a peak plasma concentration of 110 ng/ml.² When abused, amphetamines may be self-administered by the oral, intravenous, or smoked route. The last route of administration is common for methamphetamine. With heavy use, addicts may ingest up to 2000 mg per day.

3.6.1.1 Absorption

Limited data are available on the GI absorption of amphetamine in humans. Beckett et al.³ reported serum concentrations of amphetamine in two healthy volunteers after a 15-mg oral dose of the D-isomer. Peak serum concentrations of 48 and 40 ng/ml were achieved at 1.25 h when the volunteers' urine was acidified. Slightly higher serum concentrations were observed (52 and 47 ng/ml) if the urine pH conditions were not controlled. Rowland⁴ observed a peak blood concentration of 35 ng/ml, 2 h after a 10-mg oral dose of D-amphetamine to a healthy 66 kg adult. The half-life for the D-isomer was 11 to 13 h compared with a 39% longer half-life for the L-isomer. If the urine was acidified, excretion was enhanced and the half-lives of both isomers were reduced to approximately 7 h.⁵ Amphetamine demonstrates a linear one-compartment open model over the dose range 20 to 200 mg.

3.6.1.2 Distribution

The plasma protein binding of amphetamine in humans is approximately 16 to 20% and is similar in drug-dependent and naive subjects.⁶ Research by Rowland⁴ and Franksson and Anggard⁶ indicated that there was a difference in the volume of distribution between non-users (3.5 to 4.6 L/kg) and drug-dependent individuals (6.1 L/kg). It has been suggested that the larger V_d observed

in drug-dependent subjects may be due to a higher tissue affinity for amphetamine in these individuals. Evidence to support this suggestion is found in studies with amphetamine-dependent animals in which higher tissue concentrations of amphetamine were found.⁷

3.6.1.3 Metabolism and Excretion

Amphetamine is metabolized by deamination, oxidation, and hydroxylation. Figure 3.6.1 illustrates the metabolic scheme for amphetamine. Deamination produces an inactive metabolite, phenylacetone, which is further oxidized to benzoic acid and then excreted in urine as hippuric acid and glucuronide conjugates. In addition, amphetamine is also converted to norephedrine by oxidation and then this metabolite and the parent compound are *p*-hydroxylated. Several metabolites, including norephedrine, its hydroxy metabolite, and hydroxyamphetamine, are pharmacologically active. The excretion of amphetamine depends on urinary pH. In healthy men who were administered 5 mg of isotopically labeled D,L-amphetamine, approximately 90% of the dose was excreted in the urine within 3 to 4 days.⁸ Approximately 70% of the dose was excreted in the 24-h urine with 30% as unchanged drug. This was increased to 74% under acidic conditions and reduced to 1% in alkaline urine. Under normal conditions, <1% is excreted as phenylacetone, 16 to 28% as hippuric acid, 4% as benzoylglucuronide, 2% as norephedrine, <0.5% as *p*-hydroxynorephedrine, and 2 to 4% as *p*-hydroxyamphetamine.⁹ L-Amphetamine is not as extensively metabolized as the D-isomer. When volunteers were orally administered 5 to 15 mg of D- or L-amphetamine, the mean excretion of unchanged D-amphetamine was 33% of the dose and that of the L-isomer was 49% of the dose.²

The metabolism of amphetamine has been studied in those presenting with amphetamine psychosis. In the presence of acidified urine, the renal elimination of amphetamine increased significantly. The intensity of the psychosis was found to correlate with the amount of basic polar metabolites excreted in the urine, such as norephedrine and *p*-hydroxyamphetamine, and not with the plasma amphetamine concentration. This suggests that these metabolites may play an important role in the development of paranoid psychosis in chronic amphetamine users.⁶

Figure 3.6.1 Metabolic pathway of amphetamine and methamphetamine.

3.6.2 Methamphetamine

D-Methamphetamine, the *N*-methyl derivative of amphetamine, was first synthesized in 1919. Methamphetamine is available in the D- and L-forms. The D-form has reportedly greater central stimulant activity than the L-isomer, which has greater peripheral sympathomimetic activity. The D-form is the commonly abused form while the L-isomer is typically found in nonprescription inhalers as a decongestant.

Although initially available as an injectable solution for the treatment of obesity, D-methamphetamine hydrochloride is currently available as conventional and prolonged release tablets. Illicit methamphetamine is synthesized from the precursors phenylacetone and *N*-methylformamide (DL mixture) or alternatively from ephedrine or pseudoephedrine by red phosphorus/acid reduction.

3.6.2.1 Absorption

Doses of 5 to 10 mg methamphetamine typically result in blood concentrations between 20 to 60 ng/ml. In one study,¹⁰ six healthy adults were orally administered a single dose of 0.125 mg/kg methamphetamine. Peak plasma concentrations were achieved at 3.6 h with a mean concentration of 20 ng/ml. In a second study, Lebish et al.¹¹ observed a peak blood concentration of 30 ng/ml, 1 h after a single oral dose of 10 mg methamphetamine to one subject. In a study by Schepers et al.¹² eight subjects were administered four oral doses of 10 mg methamphetamine hydrochloride as sustained release tablets within 7 days. At 3 weeks later five subjects received four oral 20-mg doses. After the first dose, methamphetamine was detected in plasma between 0.25 and 2 h, the c_{\max} was 14.5 to 33.8 ng/ml (10 mg dose) and 26.2 to 44.3 ng/ml (20 mg) and occurred within 2 to 12 h. Methamphetamine was first detected in oral fluid in this study 0.08 to 2 h post dose, with a c_{\max} of 24.7 to 312.2 and 75.3 to 321.7 ng/ml after the 10 and 20 mg doses, respectively. Peak methamphetamine concentrations in oral fluid occurred at 2 to 12 h and the median oral fluid-plasma concentration ratio was 2.0 for 24 h. In general, the detection window for drug in oral fluid exceeded that in plasma.

3.6.2.2 Metabolism and Excretion

In humans, both the D- and L-forms undergo hydroxylation and *N*-demethylation to their respective *p*-hydroxymethamphetamine and amphetamine metabolites. Amphetamine is the major active metabolite of methamphetamine. Under normal conditions, up to 43% of a D-methamphetamine dose is excreted unchanged in the urine in the first 24 hours and 4 to 7% will be present as amphetamine. In acidic urine, up to 76% is present as parent drug¹⁰ compared with 2% under alkaline conditions. Approximately 15% of the dose was present as *p*-hydroxymethamphetamine and the remaining minor metabolites were similar to those found after amphetamine administration. Urine concentrations of methamphetamine are typically 0.5 to 4 mg/L after an oral dose of 10 mg. However, methamphetamine and amphetamine urine concentrations vary widely among abusers. Lebish et al.¹¹ reported urine methamphetamine concentrations of 24 to 333 mg/L and amphetamine concentrations of 1 to 90 mg/L in the urine of methamphetamine abusers.

L-Methamphetamine is biotransformed in a similar manner to the D-isomer but at a slower rate. Following a 13.7 mg oral dose, the 24 h urine contained an average of 34% of the dose as L-methamphetamine and 1.7% of the dose as L-amphetamine.³ Oyler et al.¹³ described the appearance of methamphetamine and amphetamine in urine after volunteers ($n = 8$) ingested 4×10 mg doses of methamphetamine hydrochloride daily for 7 days followed by 4×20 mg daily several weeks later. Parent and metabolite were generally detected in the first or second void post dose in a concentration range of 82 to 1827 and 12 to 180 ng/ml, respectively. Peak methamphetamine urine concentrations (1871 to 6004 ng/ml) occurred within 1.5 to 60 h after a single dose.

D-Methamphetamine is commonly self-administered by the smoked route. Both the free-base and hydrochloride salt of methamphetamine are volatile and >90% of parent drug can be recovered intact when heated to temperatures of 300°C. When cigarettes containing tobacco mixed with methamphetamine were pyrolyzed, amphetamine, phenylacetone, dimethylamphetamine, and *N*-cyanomethyl methamphetamine were the major resulting products.¹⁴ Cook¹⁵ conducted a study in which six volunteers were administered 30 mg D-methamphetamine from a pipe that was heated to approximately 300°C. Blood samples and physiological and subjective measures were collected after drug administration. Plasma methamphetamine concentrations rose rapidly after the start of smoking. However, concentrations plateaued (40 to 44 ng/ml) after 1 h with a slight increase in concentration over the next 1 h. Thereafter, concentrations in plasma declined slowly, reaching the same concentration at 8 h on the downward side of the curve as reached at 30 min on the upward side. The authors used a noncompartmental model to determine an average elimination half-life of 11.7 h with a range of 8 to 17 h. These authors also administered methamphetamine (0.250 mg/kg) orally and the resulting plasma data were fit to a one-compartment model with first-order elimination and a lag time. A maximum plasma concentration of 35 to 38 ng/ml was achieved at 3.1 h with a terminal elimination half-life of 10 h. Although the plasma concentration time curves for smoked and oral methamphetamine appeared similar, the subjective effects were markedly different, with a greater “high” being reported after smoked methamphetamine. This indicates that it may be the rate of change of plasma drug concentrations that is a significant factor in determining subjective effects. Other investigators¹⁶ have reported the bioavailability of methamphetamine after intranasal and smoked drug to be 79 and 67% (of estimated delivered dose), respectively. Maximum blood concentrations of parent drug occurred at 2.7 and 2.5 h after intranasal and smoked doses ($n = 8$).

3.6.3 3,4-Methylenedioxyamphetamine

3,4-Methylenedioxyamphetamine (MDA) is a potent psychotropic amphetamine derivative first synthesized in 1910 (Figure 3.6.2). It has no accepted medical use but is self-administered orally or intravenously in doses of 50 to 250 mg for illicit use.¹⁰ Blood concentrations following normal use have not been reported and, to date, there are no reported clinical studies delineating the pharmacokinetic or pharmacodynamic characteristics of this drug. Blood concentrations in humans have been reported following overdose. The average blood concentration in 12 fatal cases was 9.3 mg/L (range 1.8 to 26).¹⁰ The metabolism of MDA in humans has not been studied, but in other animals MDA is metabolized by *O*-dealkylation, deamination, and conjugation.¹⁷ Polymorphically expressed CYP2D6 is the major isozyme catalyzing the metabolic steps in the metabolism of MDA and MDMA.¹⁸

3.6.4 3,4-Methylenedioxymethamphetamine

3,4-Methylenedioxymethamphetamine (MDMA) is a ring-substituted derivative of methamphetamine (Figure 3.6.2) that has widespread use as a recreational drug. Self-administration is typically by the oral route in doses of 100 to 150 mg. Helmlin et al.¹⁹ reported a mean peak plasma

Figure 3.6.2 Structures of MDA and MDMA.

MDMA concentration of 300 ng/ml at 2.3 h after an oral dose of 1.5 mg/kg to adult subjects; de la Torre et al. studied eight healthy volunteers and reported a peak MDMA concentration of 180 ng/ml occurring 1.8 h after a 75-mg oral dose, with an MDA peak of 78 ng/ml 5 h after administration. MDMA presents nonlinear pharmacokinetics. In a randomized double blind cross-over placebo-controlled study with nine healthy male subjects, Farre et al.²⁰ reported increased plasma MDMA concentrations after a second dose of 100 mg, 24 h after the initial dose, were greater than expected by accumulation. The authors suspected the reason to be due to metabolic inhibition. Parameters such as blood pressure, heart rate, and subjective effects were higher after the second dose than after the first.

MDMA is metabolized to MDA with 65% of the dose excreted as parent drug within 3 days. Both MDMA and MDA are hydroxylated to mono- and di-hydroxy derivatives and subsequently conjugated before elimination. The plasma half-life has been reported to be 7.6 h.¹⁰

If MDMA is co-administered with ethanol, as 100 mg plus 0.8g/kg ethanol, plasma concentrations of the former demonstrate a 13% increase compared with MDMA administered alone.²¹ Plasma concentrations of ethanol decreased 9 to 15% after MDMA administration ($n = 9$).

MDMA has also been reported in alternative biological specimens. After a single oral dose of 75 mg in human volunteers, MDMA concentrations in oral fluid exceeded those in plasma with a mean peak concentration of 1215 ng/ml ($n = 12$) and a range of 50 to 6982 ng/ml compared with an average peak plasma concentration of 178 ng/ml (range 21 to 295 ng/ml).²² In sweat the average concentration was 25 ng/wipe when measured 4 to 5 h after ingestion of a similar dose.²³ When MDMA and MDA concentrations measured in ante-mortem samples have been compared, consistent and significant increases in the postmortem concentrations have been observed.²⁴

3.6.5 Barbiturates

Barbituric acid, 2,4,6-trioxohexahydropyrimidine, was first synthesized in 1864.¹ In 1903 it was marketed for use as an antianxiety and sedative hypnotic medication. Barbituric acid is without CNS depressant activity but by substituting an aryl or alkyl group on C-5, anxiolytic and sedative properties may be conferred. Substitution of sulfur on C-2 produces the thiobarbiturates, which have characteristically greater lipophilicity. Generally, structural changes that increase lipophilicity result in decreased duration of action, decreased latency to onset of action, increased biotransformation, and increased hypnotic potency.² Although the use of barbiturates as sedative-hypnotic agents has largely been replaced by the benzodiazepines, the barbiturates maintain an important role as anticonvulsant and anesthetic drugs.

3.6.5.1 Pharmacology

As a class of drugs, barbiturates exert hypnotic, sedative, anxiolytic, anticonvulsant, and anesthetic properties. The clinical use of these drugs is based on their shared properties and also unique properties of individual drugs within this class.¹ As CNS depressants, barbiturates exert effects on excitatory and inhibitory synaptic neurotransmission. Barbiturates are known to decrease excitatory amino acid release and post-synaptic response in experimental animals by blocking the

excitatory glutamate response. This may be due to a direct effect on the glutamate sensitive channel, or an indirect effect on calcium channels.¹ The ultra short acting barbiturates used for anesthesia, such as thiopental, depress excitatory neuronal transmission to a greater extent than the anticonvulsant barbiturates.³

Barbiturates also exert an effect on gamma-amino butyric acid (GABA) neurotransmission. Barbiturates, such as pentobarbital, enhance the binding of GABA to GABA_A receptors. This effect occurs both in the CNS and the spinal cord. The enhanced action of GABA depresses both normal physiological processes, such as post-synaptic potential evocation, and pathophysiological processes such as seizures.¹ Barbiturates also enlarge GABA-induced chloride currents by extending the time for chloride channel opening.³ It is important to note that some barbiturates such as 5-(1,3-dimethylbutyl)-5-ethyl barbituric acid (DMBB) promote convulsions by directly depolarizing the neuronal membrane and increasing transmitter release.

3.6.5.2 Absorption

When utilized as sedative hypnotics, barbiturates are administered orally. They are rapidly and completely absorbed by this route with nearly 100% bioavailability and an onset of action ranging from 10 to 60 min.³ Sodium salts are more rapidly absorbed than free acids. Intramuscular injections of sodium salts should be made deep into the muscle to prevent pain and tissue damage. Some barbiturates are also administered rectally; barbiturates utilized for the induction and maintenance of anesthesia (thiopental) or for treating status epilepticus (phenobarbital) are administered intravenously.

Pentobarbital is a short-acting barbiturate available for oral, intramuscular, rectal, and intravenous administration. After a single oral dose of 100 mg, peak serum concentrations of 1.2 to 3.1 mg/L were achieved at 0.5 to 2.0 h.⁴ These concentrations diminished slowly to an average of 0.3 mg/L at 48 h. When administered intravenously, in a 5-min continuous infusion of 50 mg, plasma concentrations averaged 1.18 mg/L ($n = 5$) at 0.08 h, declining to 0.54 mg/L after 1 h and reaching 0.27 mg/L after 24 h.⁵ Repeated intravenous doses of pentobarbital, typically 100 to 200 mg every 30 to 60 min, are administered to reduce intracranial pressure and decrease cerebral oxygen demand in patients with severe head trauma or anoxic brain damage.⁶ Doses are adjusted to maintain plasma concentrations between 25 to 40 mg/L.

Amobarbital is a barbituric acid derivative of intermediate duration of action. It is administered orally in doses of 15 to 200 mg as a sedative hypnotic and in ampoules of 65 to 500 mg for intravenous and intramuscular injection for the seizure control.⁶ Following a single oral dose of 120 mg, peak serum concentrations averaged 1.8 mg/L after 2 h.⁷ After an oral dose of 600 mg distributed over a 3-h period, the peak blood concentration was achieved after 30 min, averaging 8.7 mg/L, with a decline to 4.1 mg/L by 18 h.⁶

Phenobarbital is utilized as a daytime sedative and anticonvulsant. It also induces several cytochrome P450 isozymes. Compared to other barbiturates, phenobarbital has a low oil/water partition coefficient, which results in slow distribution into the brain. It is available for oral, intravenous, or intramuscular administration. Doses for epileptic patients range from 60 to 200 mg per day. After a single oral dose of 30 mg, peak serum concentrations averaged 0.7 mg/L ($n = 3$). Repeated doses over a period of 7 days resulted in an average peak concentration of 8.1 mg/L.⁶ Chronic administration of 200 mg per day as anticonvulsant medication resulted in an average blood concentration of 29 mg/L (range = 16 to 48 mg/L).⁹

3.6.5.3 Distribution

Barbiturates are generally widely distributed throughout the body. The highly lipophilic barbiturates, especially those used to induce anesthesia, undergo redistribution when administered intravenously. Barbiturates enter less vascular tissues over time, such as muscle and adipose tissue,

and this redistribution decreases concentrations in the blood and brain. With drugs such as thio-pental, this redistribution results in patients waking up within 5 to 15 minutes after injection of a anesthetic dose.

Pentobarbital is 65% plasma protein bound with a volume of distribution of 0.5 to 1.0 L/kg.⁶ After intravenous administration, estimates of the plasma half-life have averaged between 20 to 30 h. Amobarbital is similar to pentobarbital in the degree of plasma protein binding (59%) with a slightly larger volume of distribution (0.9 to 1.4 L/kg). The plasma half-life, however, is dose dependent, with a range of 15 to 40 h.⁶ Phenobarbital is approximately 50% plasma protein bound with a volume of distribution of 0.5 to 0.6 L/kg. The plasma half-life averages 4 days with a range of 2 to 6 days.

3.6.5.4 Metabolism and Elimination

Generally, barbiturates are metabolized by oxidation and conjugation in the liver prior to renal excretion. The oxidation of substituents at the C-5 position is the most important factor in terminating pharmacological activity.² Oxidation of barbiturates results in the formation of alcohols, phenols, ketones, or carboxylic acids with subsequent conjugation with glucuronic acid. Other metabolic transformations include *N*-hydroxylation, desulfuration of thiobarbiturates to oxybarbiturates, opening of the barbituric acid ring, and *N*-dealkylation of *N*-alkylbarbiturates to active metabolites, e.g., mephobarbital to phenobarbital.²

Pentobarbital is biotransformed by oxidation of the penultimate carbon of the methyl butyl side-chain to produce a mixture of alcohols, and by *N*-hydroxylation. The alcoholic metabolites of pentobarbital are pharmacologically inactive. Approximately 86% of a radioactive dose is excreted in the urine in 6 days, about 1% as unchanged drug and up to 73% as the *L*- and *D*-diastereoisomers of 3'-hydroxypentobarbital in a 5.4:1 ratio, and up to 15% as *N*-hydroxypentobarbital.⁸ None of these metabolites is eliminated as a conjugate.

Amobarbital is extensively metabolized to polar metabolites in a process that is saturable and best described by zero-order kinetics at therapeutic doses.¹⁰ Two major metabolites are produced by hydroxylation and *N*-glycosylation. 3'-Hydroxyamobarbital possesses pharmacological activity. Approximately 92% of a single dose is excreted in the urine with 5% excreted in the feces over a 6-day period. Approximately 2% is excreted unchanged in the urine, 30 to 40% is excreted as free 3'-hydroxyamobarbital, 29% as *N*-glycosylamobarbital, and 5% as the minor metabolite, 3'-carboxyamobarbital.

Phenobarbital is primarily metabolized via *N*-glycosylation and by oxidation to form *p*-hydroxyphenobarbital followed by conjugation with glucuronic acid (Figure 3.6.3). A dihydrohydroxy

Figure 3.6.3 Metabolic pathway of phenobarbital.

metabolite has been identified in minor amounts, thought to arise from an epoxide intermediate.¹¹ Approximately 80% of a single labeled dose is excreted in the urine within 16 days. Unchanged drug accounts for 25 to 33% of the dose, *N*-glucosyl-phenobarbital for 24 to 30%, and free or conjugated *p*-hydroxyphenobarbital for 18 to 19%.¹² When administered chronically, approximately 25% of the dose is excreted unchanged in the 24-h urine with 8% free and 9% conjugated *p*-hydroxyphenobarbital.

3.6.6 Benzodiazepines

The benzodiazepines are among the most commonly encountered prescribed drugs in forensic analysis. It has been estimated that between 10 and 20% of the adult population in the Western world has ingested these drugs within any year.¹ They are prescribed for the treatment of anxiety or panic disorder, and as a sleeping aid, anticonvulsant, or muscle relaxant. Abuse of this family of drugs is observed primarily in two forms: persistent therapeutic use, i.e., use longer than generally recommended; and illicit use, in which the drug is self-administered without physician approval or supervision. The former type of abuse is common and typically involves use at low doses compared to the rarely encountered illicit use that may involve high doses and clear indications of acute intoxication and impairment.²

3.6.6.1 Pharmacology

Benzodiazepines exert central depressant effects on spinal reflexes, in part mediated by the brainstem reticular system.³ For example, chlordiazepoxide depresses the duration of electrical

after-discharge in the limbic system. Most benzodiazepines elevate the seizure threshold and therefore may be used as anticonvulsant medications. Diazepam, clonazepam, and clorazepate may be prescribed for this therapeutic purpose.

Benzodiazepines potentiate the inhibitory effects of GABA and neurophysiological studies have identified specific benzodiazepine binding sites in the cerebellum, cerebral cortex, and limbic system.⁴ These sites are located in a complex protein macromolecule that includes GABA_A receptors and a chloride channel. Binding of benzodiazepines is modulated by both GABA and chloride. Several benzodiazepine antagonists, such as flumazenil, and inverse agonists (compounds with opposite physiological effects to benzodiazepines), such as ethyl- β -carboline-3-carboxylate, competitively inhibit the binding of benzodiazepines.

Benzodiazepines are used as hypnotics because they have the ability to increase total sleep time. They demonstrate minimal cardiovascular effects, but do have the ability to increase heart rate and decrease cardiac output. Most CNS depressants, including the benzodiazepines, exhibit the ability to relax skeletal muscles. Clozapine, a dibenzodiazepine, is used in the treatment of schizophrenia. It has both sedative and antipsychotic actions, and is the only FDA-approved medication indicated for treatment-resistant schizophrenia, and for reducing the risk of suicidal behavior in patients with schizophrenia. This drug can have potentially life-threatening side effects, but appears to have no abuse potential and will not be considered further.

3.6.6.2 Absorption

The benzodiazepines comprise a large family of lipophilic acids (diazepam $pK_a = 3.4$) with high octanol/water coefficients. They demonstrate a wide range of absorption rates when orally administered. Diazepam is absorbed rapidly, with peak concentrations occurring in 1 h in adults and as rapidly as 15 to 30 min in children. Following a single oral dose of 10 mg, peak blood diazepam concentrations averaged 148 ng/ml at 1 h, declining to 37 ng/ml by 24 h.⁵ Bioavailability is dependent on drug formulation and route of administration, with approximately 100% bioavailability of diazepam when administered orally as tablets or in suspension, decreasing to 50 to 60% when administered intramuscularly or as suppositories. The rapid rate of absorption may be explained in part by the lipophilicity of diazepam. In contrast, less lipophilic benzodiazepines, such as lorazepam, exhibit slower rates of absorption, with an average time to peak blood concentration of 2 h. Prazepam and clorazepate act as prodrugs and are decarboxylated in the stomach to nordiazepam. Consequently, absorption is slowed and a delay occurs to the onset of action of these drugs.

3.6.6.3 Distribution

The benzodiazepines exhibit a two-compartment pharmacokinetic model.⁶ Central compartment distribution is rapid and a slower distribution occurs into less perfused tissues, such as adipose. One-compartment pharmacokinetic models have been described for some benzodiazepines, such as lorazepam.⁵ It is obvious that the more lipophilic benzodiazepines distribute more rapidly than less lipophilic drugs. Therefore, after a single dose, diazepam, a highly lipophilic drug, will have a shorter duration of action than lorazepam because it will be rapidly redistributed throughout the body. This may not be easily understood when considering the half-life because diazepam has a longer half-life (approximately 30 h) than lorazepam (12 to 15 h). Therefore, a long elimination half-life does not necessarily imply long duration of action after a single dose.

The majority of benzodiazepines are highly bound to plasma proteins (85 to 95%) with apparent volumes of distribution ranging from 1 to 3 L/kg³ due to rapid removal from plasma to brain, lungs, and adipose tissue.

Figure 3.6.4 Metabolic pathway of the benzodiazepines.

3.6.6.4 Metabolism and Elimination

The benzodiazepines are extensively metabolized producing multiple metabolites, many of which share common pathways (Figure 3.6.4). Metabolic processes include hydroxylation, demethylation, and glucuronidation.

Diazepam undergoes *N*-demethylation to an active metabolite, nordiazepam. Both of these compounds are then hydroxylated to temazepam and oxazepam, respectively. These metabolites are also active, but are usually rapidly excreted and do not accumulate in plasma. Only small amounts of diazepam and nordiazepam are detected in urine, with 33% of a dose excreted as oxazepam glucuronide and another 20% excreted as various conjugates.⁵ Oxazepam, the 3-hydroxy metabolite of nordiazepam, is rapidly conjugated with glucuronic acid to form an inactive metabolite. This conjugate accounts for 61% of an oral dose in the 48-h urine. Trace amounts of free drug are detected in the urine and other hydroxylation products account for less than 5% of a dose.⁷ Lorazepam is also rapidly conjugated, forming the inactive product, lorazepam glucuronide. This conjugate is not rapidly excreted but may achieve plasma concentrations exceeding the parent drug, with an elimination half-life of approximately 16 h.⁵ Approximately 75% of a dose is eliminated in the urine as the conjugate over 5 days. Minor metabolites, such as ring hydroxylation products and quinazoline derivatives, constitute another 14% of the dose. Trace amounts of free drug are found in urine.

Chlordiazepoxide is metabolized to four active metabolites. The drug is *N*-demethylated to norchlordiazepoxide, then deaminated to form demoxepam. These metabolites demonstrate phar-

macological activity similar to the parent drug. Demoxepam is reduced to form nordiazepam, which accumulates in plasma with multiple dosing. Nordiazepam is then hydroxylated to produce oxazepam. Less than 1% of the dose is excreted unchanged in the urine with approximately 6% excreted as demoxepam and the rest as glucuronide conjugates.⁸ Temazepam undergoes *N*-demethylation to form the active metabolite oxazepam. Both parent and metabolite are subsequently conjugated. An average of 82% of a dose is excreted in urine and 12% in the feces.⁵

Alprazolam, a triazolobenzodiazepine, is also extensively metabolized by oxidation and conjugation. Metabolites include *a*-hydroxyalprazolam, 4-hydroxyalprazolam, and *a*,4-dihydroxyalprazolam. The first two metabolites possess approximately 66 and 19% of the pharmacological activity of the parent, respectively. 3-Hydroxy-5-methyltriazolyl, an analogue of chlorobenzophenone, is also formed. Approximately 94% of a dose is excreted within 72 h with 80% excreted in the urine.⁹ Flunitrazepam, the *N*-methyl-2'-fluoro analogue of nitrazepam, undergoes biotransformation via *N*-demethylation, 3-hydroxylation, and glucuronidation. In addition, the nitro group is reduced to an amine and is subsequently acetylated. Approximately 84% of a labeled dose is excreted in the urine over 1 week, and 11% is excreted in the feces.⁵ Less than 0.5% is excreted unchanged. Norflunitrazepam and 7-aminoflunitrazepam may be detected in plasma for 1 day after a single dose of 2 mg. Triazolam is extensively metabolized by hydroxylation and subsequent conjugation. The major metabolite, 1-hydroxymethyltriazolam, possesses pharmacological activity. Only trace amounts of unchanged drug are excreted in the urine, with approximately 80% of a dose appearing in the urine in 72 h, mainly as glucuronide conjugates.

Since benzodiazepines are metabolized by the cytochrome P450 family of isozymes,¹ potential inhibitors of these may produce significant increases in blood concentrations of benzodiazepines. An example of this inhibition is the drug midazolam, administered as a pre-surgical anesthetic. Lam et al.¹¹ reported a mean increase in the area under the curve of midazolam by ketoconazole (772%) and nefazodone (444%) in a group of 40 healthy human subjects administered 200 mg ketoconazole per day and 400 mg nefazodone per day. The authors concluded that caution should be exercised when use of midazolam is warranted with potent CYP3A4 inhibitors.¹¹

3.6.7 Cocaine

Cocaine is a naturally occurring alkaloid obtained from the plant *Erythroxylon coca* L. This plant grows in the Andes region of South America, ideally at elevations between 1500 and 5000 ft.¹ A second closely related species has been identified, *Erythroxylon novogranatense* H., and each species has one variety known as *E. coca* var. *ipadu* Plowman and *E. coca novogranatense* var. *truxillense*, respectively. Cocaine may also be chemically synthesized with cold aqueous succinaldehyde and cold aqueous methylamine, methylamine hydrochloride, and the potassium salt of acetone-dicarboxylic acid monomethyl ester.²

Cocaine is used medically by otorhinolaryngologists and plastic surgeons as an epinephrine cocaine mixture. Solutions for topical application are typically less than 4% cocaine hydrochloride. In the U.S. cocaine is a scheduled drug under the federal Controlled Substances Act of 1970. Refined cocaine, in the form of the base or hydrochloride salt, is self-administered by many routes, including snorting, smoking, genital application, and by injection.

3.6.7.1 Pharmacology

Cocaine inhibits the presynaptic reuptake of the neurotransmitters norepinephrine, serotonin, and dopamine at synaptic junctions. This results in increased concentrations in the synaptic cleft. Since norepinephrine acts within the sympathetic nervous system, increased sympathetic stimulation is produced. Physiological effects of this stimulation include tachycardia, vasoconstriction, mydriasis, and hyperthermia.³ CNS stimulation results in increased alertness, diminished appetite, and increased energy. The euphoria or psychological stimulation produced by cocaine is thought to be related to the inhibition of serotonin and dopamine reuptake. Cocaine also acts as a local anesthetic due to its ability to block sodium channels in neuronal cells.³

3.6.7.2 Absorption

Cocaine is rapidly absorbed from mucous membranes and the pulmonary vasculature. However, the rate at which cocaine appears in the blood is dependent on the route of administration. Coca leaves have been chewed by native South Americans for more than 3000 years. Recent studies of the oral route of administration found that chewing powdered coca leaves containing between 17 and 48 mg of cocaine produced peak plasma concentrations of 11 to 149 ng/ml ($n = 6$) at 0.4 to 2 h after administration.⁴ In another study, healthy male volunteers were administered cocaine hydrochloride (2 mg/kg) in gelatin capsules. Peak plasma concentrations of 104 to 424 ng/ml were achieved at 50 to 90 min. One of the most common routes of self-administration of cocaine in North America is the intranasal route. Wilkinson et al.⁵ found that peak plasma concentrations of cocaine were reached 35 to 90 min after “snorting” but another study using equivalent doses found that peak plasma concentrations were achieved between 120 and 160 min.⁶ Intravenous administration of 32-mg cocaine hydrochloride resulted in an average peak plasma concentration of 308 ng/ml at 5 min.⁶ Cocaine may also be self-administered by the smoked route in the form of cocaine base, commonly called “crack” or by a process known as “free-basing” in which powdered cocaine hydrochloride is converted into its base form. In a study of six subjects who each smoked 50 mg of cocaine, the average peak plasma cocaine concentration of 203 ng/ml was achieved at 5 min.⁷ The bioavailability of cocaine after smoking depends on several factors including the temperature of volatilization and drug loss in main- and sidestream smoke.

Perez-Reyes et al.⁸ estimated that only 32% of a dose of cocaine base placed in a pipe is actually inhaled by the smoker. Cone⁹ compared the pharmacokinetics and pharmacodynamics of cocaine by the intravenous, intranasal, and smoked routes of administration in the same subjects. Venous plasma cocaine concentrations peaked within 5 min by the intravenous and smoked routes. Estimated peak cocaine concentrations ranged from 98 to 349 ng/ml and 154 to 345 ng/ml after intravenous administration of 25-mg cocaine hydrochloride and 42-mg cocaine base by the smoked route, respectively. After dosing by the intranasal route (32 mg cocaine hydrochloride) estimated peak plasma cocaine concentrations ranged from 40 to 88 ng/ml after 0.39 to 0.85 h.⁹ In this study, the average bioavailability of cocaine was 70.1% by the smoked route, and 93.7% by the intranasal route. Jenkins et al.¹⁰ described the correlation between pharmacological effects and plasma cocaine concentrations in seven volunteers after they had smoked 10 to 40 mg cocaine. The mean plasma cocaine concentration 2 min after smoking 40 mg cocaine was 153 ± 107.5 ng/ml. Peak concentrations ranged from 160.8 ± 99.1 ng/ml. Increases in pupil diameter, systolic and diastolic blood pressure, heart rate, and subjective measures of drug effect occurred early after drug administration, with maximum effects observed at 2 min (first measure) for blood pressure and subjective measures, or after a brief delay (at 5 to 10 min post dose) for others, notably heart rate and pupil diameter.

3.6.7.3 Distribution

After an intravenous dose of radiolabeled cocaine to rats, the highest concentrations were found in the brain, spleen, kidney, and lung after 15 min, with the lowest concentrations in the blood, heart, and muscle.¹¹ Plasma protein binding in humans is approximately 91% at low concentrations.¹¹ Cocaine binds to the plasma protein, albumin, and also to α 1-acid glycoprotein. The steady-state volume of distribution is large (1.6 to 2.7 L/kg), reflecting extensive extravascular distribution.¹² In 1991 Ambre et al.¹³ studied the pharmacokinetics of benzoylecgonine in nine human volunteers. The metabolite is much more polar than the parent and lipophobic, explaining why the measured mean V_d was only 0.71.

A two-compartment open linear model has been described for the pharmacokinetic profile of cocaine after intravenous administration.¹⁴ The distribution phase after cocaine administration is rapid and the elimination half-life estimated as 31 to 82 min.¹⁴ Cone⁹ fitted data to a two-compartment model with bolus input and first-order elimination for the intravenous and smoked routes. For the intranasal route, data were fitted to a two-compartment model with first-order absorption and first-order elimination. The average elimination half-life ($t_{1/2\beta}$) was 244 min after intravenous administration, 272 min after smoked administration, and 299 min after intranasal administration.

The disposition of cocaine in nontraditional testing matrices has been described. For example, Lester et al.¹⁵ measured cocaine and benzoylecgonine (BE) concentrations in skin, interstitial fluid (IF), sebum, and stratum corneum in five volunteers after the intravenous 1-h infusion of 1 mg/kg cocaine d_5 . Peak cocaine concentrations in the skin were achieved at 1.5 h and were undetectable after 6 h. No BE was measured in the skin. Peak cocaine concentrations were achieved at 5 h after administration in the IF and were nondetectable by 24 h. BE was found in the IF. In the sebum peak cocaine concentrations occurred between 3 to 24 h but in the stratum corneum cocaine was detected in only one subject.

3.6.7.4 Metabolism

In humans, the principal route of metabolism of cocaine is by hydrolysis of the ester linkages. Pseudocholinesterase and liver esterases produce the inactive metabolite, ecgonine methyl ester (EME) (Figure 3.6.5). The second major metabolite, BE, is formed spontaneously at physiological pH. In addition, there is evidence that BE may be formed enzymatically from cocaine by liver carboxylesterases. *N*-Demethylation of BE produces benzoynorecgonine. Further metabolism of EME and BE produces ecgonine. Further hydrolysis of cocaine and BE produce minor metabolites,

Figure 3.6.5 Metabolic pathway of cocaine.

meta- and para-hydroxy-cocaine and -BE. The proportion of each metabolite produced and the activity of the individual metabolites have yet to be completely determined.

Cocaine may be *N*-demethylated by the cytochrome P450 system to produce an active metabolite, norcocaine. Further breakdown produces *N*-hydroxynorcocaine and norcocaine nitroxide. Further metabolism produces a highly reactive free radical that is thought to be responsible for the hepatotoxicity observed in cocaine users.¹

When cocaine is coadministered with ethanol, cocaethylene (CE) is formed in the liver by transesterification by liver methylesterase. CE may also be formed by fatty acid ethyl synthase.¹⁶ This lipophilic compound crosses the blood–brain barrier and is known to contribute to the psychological effects produced by cocaine.¹ Harris et al.¹⁷ administered deuterium-labeled cocaine (0.3 to 1.2 mg/kg) intravenously 1 h after an oral dose of ethanol (1 g/kg) to ten volunteers. When coadministered with ethanol, $17 \pm 6\%$ (mean \pm S.D.) of the cocaine was converted to cocaethylene. Ethanol ingestion prior to cocaine administration decreased urine BE levels by 48%. When cocaine is smoked, a pyrolysis product, anhydroecgonine methyl ester (AEME), is formed. Therefore, the presence of this compound indicates exposure to smoked cocaine. The pharmacological and toxicological properties of this compound have not been studied.

3.6.7.5 Elimination

Approximately 85 to 90% of a cocaine dose is recovered in the 24-h urine.¹⁸ Unchanged drug accounts for 1 to 9% of the dose depending on urine pH, BE, 35 to 54%, and EME, 32 to 49%. In one study, excretion data were obtained from subjects administered a bolus intravenous injection of cocaine followed by an intravenous infusion, supplying total doses of 253, 444, and 700 mg cocaine.¹⁹ Elimination half-lives averaged 0.8, 4.5, and 3.1 h, for cocaine, BE, and EME, respec-

tively. After intranasal application of 1.5 mg/kg, urine cocaine concentrations averaged 6.7 mg/L during the first hour, and BE concentrations peaked between 4 to 8 hours at 35 mg/L.¹¹ Oral ingestion of 25 mg cocaine by a single individual resulted in a peak urine BE concentration of 7.9 mg/L in the 6- to 12-h collection period, with a decline to 0.4 mg/L by 48 h.²⁰ Oral consumption of coca tea of Peruvian origin containing approximately 4 mg of cocaine resulted in a peak urine BE concentration of 3.9 mg/L after 10 h in one individual.²¹ The cumulative urinary excretion of BE after approximately 48 h was 3.1 mg. Consumption of coca tea of Bolivian origin by the same individual, containing a similar amount of cocaine, resulted in a peak urine BE level of 4.9 mg/L at 3.5 h.²¹ The cumulative BE excreted in urine was 2.6 mg. The minor metabolites, including the *p*- and *m*-hydroxy metabolites, and also the pyrolysis product, AEME, have been detected in urine after cocaine administration.^{22,23}

3.6.8 Lysergic Acid Diethylamide

Lysergic acid diethylamide (LSD) is an indolealkylamine discovered by Albert Hoffman of Sandoz Laboratories in 1943.¹ It may be synthesized from lysergic acid and diethylamine. Lysergic acid, a naturally occurring ergot alkaloid, is present in grain parasitized by the fungus *Claviceps purpurea*. A closely related alkaloid, lysergic acid amide, is present in morning glory seeds and the Hawaiian baby wood rose.¹ In the 1950s, LSD was used as an aid in the treatment of alcoholism, opioid addiction, psychoneurosis, and sexual disorders, but currently it is classified under Schedule I of the federal Controlled Substances Act with no accepted medical use in the U.S. It is available illicitly as a powder, tablet, or gelatin capsule, or impregnated in sugar cubes, gelatin squares, blotter paper, or postage stamps.

3.6.8.1 Pharmacology

LSD is a potent centrally acting drug. The D-isomer is pharmacologically active while the L-isomer is apparently inactive.¹ Neuropharmacological studies have shown that LSD exerts a selective inhibitory effect on the brain's raphe system by causing a cessation of the spontaneous firing of serotonin-containing neurons of the dorsal and median raphe nuclei. In this way, LSD acts as an indirect serotonin antagonist. However, inhibition of raphe firing is not sufficient to explain the psychotomimetic effects of LSD because the compound lisuride is a more potent inhibitor of the raphe system yet does not demonstrate hallucinogenic potential in humans. Therefore, other post-synaptic mechanisms such as action on glutamate or serotonin receptors may be involved.² Also, there is evidence that LSD indirectly exerts effects on the cytoskeleton by reducing the amount of serotonin released by the raphe system.³ LSD produces sympathomimetic, parasympathomimetic, and neuromuscular effects, which include mydriasis, lacrimation, tachycardia, and tremor.

3.6.8.2 Absorption

LSD may be self-administered orally, nasally, or by parenteral ingestion; however, the oral route is the most common. Doses of 50 to 300 µg are ingested, with a minimum effective dose of 20 to 25 µg. Absorption is rapid and complete regardless of the route of administration. However, food in the stomach slows absorption when ingested. Effects are observed within 5 to 10 min, with psychosis evident after 15 to 20 min. Peak effects have been reported 30 to 90 min after dosing; effects decline after 4 to 6 h.⁵ The duration of effects may be 8 to 12 h.

Pharmacokinetic studies in humans are limited with much of the data dating from the 1960s. Following intravenous administration of 2 µg/kg, a peak plasma LSD concentration of 5 ng/ml was observed after 1 h.¹ At 8 h, the plasma concentration had declined to 1 ng/ml.¹ In much more recent studies a method using liquid chromatography with electrospray ionization and tandem mass spectrometric detection has been developed and validated for LSD and iso-LSD. Using this technique the lower limit for quantitative determination was 0.02 µg/L for LSD and iso-LSD. Peak plasma levels were slightly higher than earlier reports (case 1 plasma LSD = 0.31 µg/L, iso-LSD = 0.27 µg/L and in a second case LSD = 0.24 µg/L, iso-LSD = 0.6 µg/L in urine).

3.6.8.3 Distribution

Plasma protein binding of LSD is >80%. As the drug penetrates the CNS, it is concentrated in the visual brain areas, and the limbic and reticular activating systems, correlating with perceived

Figure 3.6.6 Metabolic pathway of LSD.

effects. LSD is also found in the liver, spleen, and lungs.⁴ The volume of distribution is reported to be low at 0.28 L/kg.¹ Wagner et al.⁶ described a two-compartment open model for LSD with an elimination half-life of 3 h.

3.6.8.4 Metabolism and Excretion

LSD metabolism was investigated using MS-MS. Metabolites were determined using MS-MS. The main metabolite was 2-oxo-3-hydroxy-LSD (O-H-LSD) present in urine at the concentrations of 2.5 and 6.6 µg/L, respectively, for case 1 and 2, but it was not detected at all in plasma. Nor-LSD was also found in urine at 0.15 and 0.01 µg/L levels. Nor-iso-LSD, lysergic acid ethylamide (LAE), trioxylated-LSD, lysergic acid ethyl-2-hydroxyethylamide (LEO), and 13- and 14-hydroxy-LSD and their glucuronide conjugates were detected in urine using specific MS-MS transitions.⁵

The metabolism and elimination of LSD in humans has received limited study. Animal studies demonstrated extensive biotransformation via *N*-demethylation, *N*-deethylation, and hydroxylation to inactive metabolites (Figure 3.6.6).⁷ In humans, demethylation and aromatic hydroxylation occur to produce *N*-desmethyl-LSD and 13- and 14-hydroxy-LSD. Hydroxylated metabolites undergo glucuronidation to form water-soluble conjugates. Excretion into the bile accounts for approximately 80% of a dose.⁴ Concentrations of unchanged drug ranged from 1 to 55 ng/ml in the 24-h urine after ingestion of 200 to 400 µg LSD in humans.⁸ LSD or its metabolites were detectable for 34 to 120 h following a 300-µg oral dose in seven human subjects.⁹ The clearance of LSD in humans is unknown.

3.6.9 Marijuana

The term “marijuana” refers to all parts of the plant *Cannabis sativa* L., whether growing or not: the seeds; resin extracted from any part of such plant; and every compound, salt, derivative or mixture; but does not include the mature stalks, fiber produced from the stalks, or oil or cake prepared from the seeds.¹ *Cannabis sativa* L. is an annual plant that grows in all parts of the world to a height of 16 to 18 ft. Commercially, it is cultivated for hemp production, with the bulk of the plant consisting of stalks with very little foliage, except at the apex. In contrast, the wild plant and those cultivated illegally possess numerous branches as the psychoactive ingredient is concentrated in the leaves and flowering tops. There may be significant differences in the gross appearance of marijuana plants due to climatic and soil conditions, the closeness of other plants during growth, and the origin of the seed. Marijuana is the crude drug derived from the plant *Cannabis sativa* L., a plant that is currently accepted as belonging to a family (Cannabaceae) that has only one genus (*Cannabis*) with only one species (*sativa*) that is highly variable.²

In 1980 the total number of natural compounds identified in *C. sativa* L. was 423³ By 1995 the number had risen to 483, and recently 6 new compounds, 4 new cannabinoids and 2 new flavonoids, have been described.⁴

The major psychoactive constituent of marijuana is delta-9-tetrahydrocannabinol, commonly referred to as THC. Different parts of the plant contain varying concentrations of THC, with leaves containing <1% to 10% THC by weight, and hashish, a resin prepared from the flowering tops, containing approximately 15% THC. THC may be synthesized using citral and olivetol in boron trifluoride and methylene chloride.⁵ Although no reports have appeared within the published peer-reviewed literature, persistent reports from the enforcement community suggest that intensive cross-breeding has led to production of plants that have a THC content well over 20%. These “super” plants appear to be grown mainly along the Canadian–American border, primarily by Asian gangs.

3.6.9.1 Pharmacology

Marijuana is typically self-administered orally or by smoking in doses of 5 to 20 mg.⁶ It may produce a variety of pharmacological effects including sedation, euphoria, hallucinations, and

temporal distortion. In addition, THC possesses activity at benzodiazepine, opioid, and cannabinoid receptors and also exerts effects on prostaglandin synthesis, DNA, RNA, and protein metabolism.^{7,8} Early workers thought that THC effects were nonspecific, but in the late 1980s a specific cannabinoid receptor was identified in the brains of rats. It is now apparent that there are two types of cannabinoid receptor — CB1 and CB2 — and these receptors are the primary targets of endogenous cannabinoids (endocannabinoids). THC binds to both cannabinoid receptors. The CB1 receptor is mostly found in the brain, while the CB2 receptor is found in immune tissues such as the spleen, thymus, and tonsils⁸ but not in the brain. Specific antagonists exist for each of the CB1 and CB2 receptors.

Cannabinoid-coupled G protein-coupled receptors are involved in the control of many processes, including metabolic regulation, craving, pain, anxiety, bone growth, and immune function. The exogenous cannabinoids found in marijuana plants can also exert effects via G(i/o) proteins, negatively modulating cyclic AMP levels, and activating the inward rectifying K(+) channels.⁹ Manipulation at either receptor site may have important clinical consequences and therapies involving cannabinoid receptors are under development. Manipulation at either receptor site may have important clinical consequences and therapies based on cannabinoid-receptor interactions are under development. Cannabinoids mediate a decrease in blood pressure and can suppress cardiac contractility in hypertension. Conversely, if the CB1-mediated cardiodepressor and vasodilator effects of anandamide are enhanced (by blocking its hydrolysis), blood pressure tends to normalize.¹⁰ Many clinical developments taking advantage of these properties are likely to occur. By the time of publication of this book, rimonabant (AcompliatTM), a C1 blocking agent, will have been approved for weight loss by the FDA.¹¹

3.6.9.2 Absorption

Marijuana is commonly self-administered by the smoked route by rolling dried marijuana leaves in tobacco paper and smoking as a cigarette. Smoking results in rapid drug delivery from the lungs to the brain. However, loss of drug occurs during the smoking process due to pyrolysis and sidestream smoke. In an *in vitro* study in which loss due to sidestream smoke was minimized, Davis et al.¹² reported a 30% loss of THC due to pyrolysis. Sidestream THC losses of 40 to 50% have been reported. Once THC reaches the lungs, it is rapidly absorbed. Peak plasma THC concentrations of 100 to 200 ng/ml occur after 3 to 8 min and THC is present in blood after the first puff from a marijuana cigarette. Mean \pm SD THC concentrations of 7.0 ± 8.1 ng/ml and 18.1 ± 12.0 ng/ml were observed after the first inhalation of low- or high-dose marijuana cigarettes (1.75%, 3.55%), respectively.¹³ Peak concentrations occurred at 9 min after the first puff. Lemberger et al.¹⁴ demonstrated that physiological and subjective measures of drug effect occurred simultaneously with the rise in blood THC concentrations.

After oral administration, THC is 90 to 95% absorbed. However, the oral route results in lower peak plasma concentrations at a later time. Perez-Reyes et al. reported a mean peak plasma THC concentration of 6 ng/ml after ingestion of 20 mg.¹⁵ Wall and Perez-Reyes noted that peak plasma THC concentrations occurred 30 min after intravenous administration of 4 to 5 mg, with a mean concentration ($n = 7$) of 62 ng/ml.¹⁶ Reported values for the bioavailability of THC after smoking have ranged from 18 to 50%.¹⁴ This wide range reflects the large inter- and intrasubject variability that occurs in smoking dynamics.¹⁸ Altering the number, duration, and spacing of puffs, the length of time the inhalation is held, and the inhalation volume or depth of puff¹⁹ may vary the amount of drug delivered. Measures to minimize the loss of side- and mainstream smoke as well as optimizing the temperature for drug volatilization will, in turn, increase the amount of drug available for delivery to the lungs. One facet of smoking that cannot be controlled by the smoker is drug deposition on non- or poorly absorbing surfaces within the body. Deposition outside of the lungs is usually a function of drug particle or vapor size. Drug may be deposited in the nasopharyngeal region or the upper bronchial tree. This reduces the amount of drug reaching the lung alveoli where rapid absorption into the blood and subsequent transport to the brain occurs.

Ohlsson et al. compared the bioavailability of THC after intravenous, smoked, and oral administration. Eleven healthy subjects were administered 5 mg intravenously, 19 mg smoked, and 20 mg orally. Plasma concentrations rose rapidly after intravenous administration, reaching 161 to 316 ng/ml at 3 min and declining rapidly thereafter. Peak plasma concentrations also occurred at 3 min after smoking, with lower concentrations of THC ranging from 33 to 118 ng/ml. The plasma concentration time curve after smoking was similar to that obtained after intravenous administration but at lower concentrations. In contrast, low THC concentrations were found after oral administration, with much higher intersubject variability. The authors determined the bioavailability of THC to be 8 to 24% after smoking compared with 4 to 12% after oral ingestion.²⁰

3.6.9.3 Distribution

THC is 97 to 99% plasma protein bound with little present in red blood cells. Due to its lipophilicity, THC distributes rapidly into tissues. Highly perfused organs, such as the brain, accumulate THC rapidly after administration, whereas THC distributes more slowly into poorly perfused tissues such as fat.²¹ Harvey et al. reported finding maximum THC concentrations in the brains of mice 30 min after a single intravenous dose. The distribution of THC into various tissues and organs such as brain, liver, heart, kidney, salivary glands, breast milk, fat, and lung is reflected in the large volume of distribution (4 to 14 L/kg).^{20,22} Hunt and Jones proposed a four-compartment model to describe four tissue composites into which THC distributes after intravenous injection.²³ They observed average half-lives of 1 min, 4 min, 1 h, and 19 h to describe these compartments. They concluded that a “pseudoequilibrium” is achieved between plasma and tissues 6 h after an intravenous dose. Thereafter, THC is slowly eliminated as THC diffuses from tissue to the blood. The terminal elimination half-life is approximately 1 day but has been reported to be 3 to 13 days in frequent users.^{24,25}

3.6.9.4 Metabolism and Excretion

Metabolism is the major route of elimination of THC from the body as little is excreted unchanged. In humans, over 20 metabolites have been identified in urine and feces.²⁶ Metabolism in humans involves allylic oxidation, epoxidation, aliphatic oxidation, decarboxylation, and conjugation. The two monohydroxy metabolites (Figure 3.6.7) 11-hydroxy (OH)-THC and 8-beta-hydroxy THC are active, with the former exhibiting similar activity and disposition to THC, while the latter is less potent. Plasma concentrations of 11-OH-THC are typically <10% of the THC concentration after marijuana smoking. Two additional hydroxy compounds have been identified, namely, 8-alpha-hydroxy-THC and 8,11-dihydroxy-THC, and are believed to be devoid of THC-like activity. Oxidation of 11-OH-THC produces the inactive metabolite, 11-nor-9-carboxy-THC, or THC-COOH. This metabolite may be conjugated with glucuronic acid and is excreted in substantial amounts in the urine.

The average plasma clearance is 600 to 980 ml/min with a blood clearance of 1.0 to 1.6 L/min, which is close to hepatic blood flow. This indicates that the rate of metabolism of THC is dependent on hepatic blood flow. Approximately 70% of a dose of THC is excreted in the urine (30%) and feces (40%) within 72 h.²⁶ Because a significant amount of the metabolites are excreted in the feces, enterohepatic recirculation of THC metabolites may occur. This would also contribute to the slow elimination and hence long plasma half-life of THC. Unchanged THC is present in low amounts in the urine and 11-OH-THC accounts for only 2% of a dose.

The remainder of the urinary metabolites consist of conjugates of THC-COOH and unidentified acidic products. Following a single smoked 10-mg dose of THC, urinary THC-COOH concentrations peaked within 16 h of smoking, at levels of 6 to 129 ng/ml ($n = 10$).²⁷ Huestis and Cone²⁵ reported a mean (\pm SEM) urinary excretion half-life for THC-COOH of 31.5 ± 1 h and 28.6 ± 1.5 h for six healthy volunteers after administration of a single marijuana cigarette containing 1.75

Figure 3.6.7 Metabolic pathway of delta-9-THC.

or 3.55% THC, respectively. Passive exposure to marijuana smoke may also produce detectable urinary metabolite concentrations. Cone et al. exposed five volunteers to the smoke of 16 marijuana cigarettes (2.8% THC content) for 1 h each day for 6 consecutive days.²⁴ After the first session, THC-COOH concentrations in urine ranged from 0 to 39 ng/ml. A maximum THC-COOH concentration of 87 ng/ml was detected in one subject on day 4 of the study.

THC may be ingested orally by consuming food products containing the seeds or oil of the hemp plant. Ingestion of 0.6 mg/day (equivalent to 125 ml hemp oil containing 5 μ g/g of THC or 300 g hulled seeds at 2 μ g/g) for 10 days resulted in urine THC-COOH concentrations of <6 ng/ml.²⁸ The maximum urinary concentration of THC-COOH in another study after ingestion of hemp oil containing 0.39 to 0.47 mg THC/day for 5 days was 5.4 to 38.2 ng/ml ($n = 7$).²⁰ After oral administration of a higher dose (7.5 and 14.8 mg THC/day) peak concentrations of THC-COOH ranged from 19.0 to 436 ng/ml. Controlled studies have shown that at the federally mandated cannabinoid cutoffs, it is possible but unlikely for a urine specimen to test positive after ingestion of manufacturer-recommended doses of low-THC hemp oils.²⁹ On the other hand, patients taking Marinol®, the synthetic form of THC approved by the FDA for the control of nausea and vomiting in cancer patients, will almost certainly test positive. Dronabinol or synthetic THC is present in Marinol® capsules and ElSohly et al. found that within 24 h of administering a single 15-mg dose of dronabinol to four subjects, peak urine THC-COOH concentrations were between 189 and 362 ng/ml.³⁰

3.6.10 Opioids

Members of the group of natural, semi-synthetic, or synthetic alkaloid compounds prepared from opium are referred to as “opioids.” This group includes natural compounds usually denoted “opiates,” such as morphine and codeine, and the synthetic and semisynthetic compounds such as oxycodone, buprenorphine, fentanyl, methadone, and tramadol. The pharmacological effects and pharmacokinetic parameters of these drugs share many common characteristics and are illustrated with the prototypic drug in this class, morphine.

Morphine is obtained from the latex of the opium poppy, *Papaver somniferum*. Morphine, codeine, and other opiates are extracted from a milky exudate that forms within 12 h when unripe seed capsules are incised. When dried, the material is called raw opium. The principal alkaloid in raw opium is morphine, constituting 8 to 19% of opium by dry weight. The actual percentage is highly dependent on growing conditions and location.¹ Morphine is the analgesic of choice for the treatment of both chronic pain syndromes and acute myocardial infarction. Whether it will remain so for long is not clear. The results of recently published observational studies strongly suggest that in patients with acute coronary syndrome, the use of morphine, either alone, or in combination with nitroglycerin, is associated with an increased mortality rate.²

Morphine remains the prototypic mu-opioid analgesic. And, even though other opioids share similar structures, there is overwhelming proof that morphine is different from other similar appearing agents. In the past, these differences had been explained by different pharmacokinetics, but now it appears that heroin and morphine act via different receptor mechanisms. As a result, the concept of multiple mu receptors has emerged. Multiple splice variants of the cloned mu-opioid receptor (abbreviated as M) R-1) have been identified. Nonetheless, a relatively large volume of pharmacokinetic data exists describing morphine clinical applications, which is reviewed here.³ It is becoming increasingly obvious that knowledge of the molecular mechanisms involved in causing drug dependence and in providing pain relief is mandatory if there are to be clinical advances.

3.6.10.1 Morphine

Pharmacology

Morphine and other related opioids produce their pharmacological effects by binding to opiate receptors located throughout the body. Three types of opiate receptor μ (mu), κ (kappa), and δ (delta) are recognized; they are approximately 70% homologous. Differences between receptors occur mainly at the N and C terminal ends. The mu receptor is thought to be the most important, because it is where morphine (and like drugs) exerts its effect. When a mu receptor binds with an agonist, such as morphine, or heroin, or oxycodone, a G protein attached to the third intracellular loop of the receptor is activated (opiate receptors have seven loops, also called transmembrane domains).⁴ The genes that determine the various receptor subtypes are located on different chromosomes. There are two mu, three kappa, and two delta subtypes. It is assumed that these receptors arise from post-translational modifications (i.e., they arise at a late stage in protein synthesis), because their genes have not been identified. A purported fourth opiates receptor, referred to as the sigma receptor, is now recognized as a completely unrelated entity.⁵

Mu receptors are almost always located proximally, on the presynaptic side of the synapse. The periaqueductal gray is the region containing the most mu receptors, but they are also found in the superficial dorsal horn of the spinal cord, the external plexiform layer of the olfactory bulb, the nucleus accumbens (an area deeply implicated in the process of addiction), in some parts of the cerebral cortex, and in some of the nuclei of the amygdala. Mu receptors avidly bind enkephalins and beta-endorphin, but they have a low affinity for dynorphins (primarily a kappa receptor agonist).⁶

The obvious clinical effects of morphine are papillary constriction due to its excitatory action on the parasympathetic nerves that supply the pupil. Respiratory depression also occurs because mu agonists exert a direct effect on brain stem respiratory centers, reducing their responsiveness to carbon dioxide. In addition, mu-stimulation depresses respiratory centers located in the pons. Small doses of morphine merely depress the respiratory rate, while large doses cause respiratory arrest, the accepted mechanism of death in cases of narcotic drug overdose. Nausea and vomiting are also associated with the use of mu receptor activation because opioids directly stimulate the chemoreceptor vomiting trigger zone in the medulla. Morphine provides effective and convenient pain relief, largely because there is no upper limit to the amount that can be given, provided enough

time is allowed for tolerance to the respiratory effects to develop. Morphine, or compounds that bind the mu receptor are also used to treat diarrhea, and the cough associated with malignancy and tuberculosis.⁷ Heroin, which is converted to morphine within the body, was originally marketed by Bayer as a cough suppressant.⁸

Activation of kappa receptors also produces analgesia, but it simultaneously induces nausea and dysphoria. Kappa receptors are located mainly on pain neurons located in the spinal cord and, to a lesser extent in the brain. They bind to an endogenously occurring ligand called dynorphin. The exact function of dynorphin is unknown, but evidence suggests that it is produced to counter the pleasurable effects of produced by cocaine and is, to some degree, neuroprotective.⁹ Some believe dynorphin may play an important role in determining an individual's risk for addiction. Blocking the actions of dynorphin helps to alleviate depression.¹⁰

Delta receptor activation also produces analgesia, but it can also cause seizures as well. Delta receptors normally bind to a class of endogenous ligand known as enkephalins, but unlike mu receptors, information about delta receptors is limited. Enkephalins are peptides that are produced by the pituitary gland. Several different enkephalins have been identified. β -Enkephalin resembles opiates because when it binds to a delta receptor, it relieves pain.¹¹

Absorption

Morphine can be given orally, or by subcutaneous, intramuscular injection, or intravenous injection.⁷ Increasingly, as the purity of street heroin has risen, heroin is also being inhaled ("chasing the dragon").¹² Heroin is also administered epidurally, either as an individual dose or continuous infusion.¹³ Parenteral morphine is well absorbed, and in individuals with normal blood pressure, resultant plasma levels after subcutaneous, intramuscular, and intravenous injection are very similar.¹⁴ The oral bioavailability of morphine is quite low due to extensive first pass hepatic metabolism. A 10-mg bolus given to healthy volunteers undergoing elective surgery produced peak blood of 200 to 400 ng/ml 5 min after injection.¹⁵ After either intramuscular or subcutaneous injection, morphine plasma levels peak in 10 to 20 min. In healthy volunteers a dose of 10 mg/70 kg given intravenously produces a free morphine concentration of 80 ng/ml at 5 min, compared to a peak of 74 ng/ml at 15 min after the same dose was given as an intravenous bolus.¹⁴ Oral administration is a mainstay in the management of patients with cancer. In stable patients receiving sufficient oral morphine to produce acceptable analgesia, the mean trough serum morphine concentration is on the order of 18 ng/ml with roughly equal concentrations of the active metabolite M6G.¹⁶

Distribution

The volume of distribution of morphine ranges from 2 to 5 L/kg in humans,¹⁷ although values as high as 7 L/kg have been reported.¹⁸ The wide variation could be explained by the health of the volunteers being studied. In patients with incompletely compensated heart failure, and increased body water from any cause, higher values would be expected. Conversely, in patients with renal failure, where intravascular volume may be decreased, smaller values would be expected. Plasma protein binding of morphine in healthy humans ranges from 12 to 35% and appears to be independent of concentration over approximately a 1000-fold range, although a slight decrease (24 to 20% bound) was observed when the concentration was increased from therapeutic by 60-fold.¹⁹ Morphine is bound mainly to albumin with approximately 5% bound to γ -globulin and 5% to α -1-acid glycoprotein. In healthy humans, the blood/plasma concentration ratio for morphine averages 1.02.¹⁷ This ratio was found to be consistent in the concentration range of 35 to 140 nM. The plasma half-life averaged 1.8 and 2.9 h in female and male surgical patients, respectively.²⁰

Morphine is relatively hydrophilic and therefore distributes slowly into tissues, where it may be detected in fat, even after death.²¹ Morphine crosses the blood-brain barrier, but not so freely as heroin and codeine, which possess an aromatic hydroxyl group at the C3 position. Morphine's

passage across the blood–brain barrier is mediated by P-glycoprotein (P-gp) concentrated in brain capillary endothelium. Drugs that interfere with P-gp, such as doxyrubrin, can alter brain morphine uptake and disposition. Lopermide, which is widely used to treat diarrheal disease, avidly binds the mu receptor but, because it does not bind to P-gp, it never enters the brain and never causes any of the psychological changes produced by morphine.²²

Metabolism and Excretion

The major pathway for morphine metabolism is conjugation with glucuronic acid (Figure 3.6.8). The free phenolic hydroxyl group undergoes glucuronidation to produce morphine-3-glucuronide (M3G), a highly water soluble metabolite. Metabolism occurs primarily in the liver with 90% of a dose excreted in the urine and 10% in the feces. There is extensive enterohepatic circulation of both conjugated and unconjugated morphine. Approximately 87% of a dose of morphine is excreted in the 72-h urine, 75% as M3G, 10% as free morphine, and the remainder as morphine-6-glucuronide, morphine-3-sulfate, normorphine, and conjugates. The clearance of morphine was found to vary between 1.2 to 1.9 L/min/70 kg in several studies of humans.¹⁹

M3G is the predominant metabolite in young children. The total body morphine clearance is 80% of an adult at 6 months of age.²³ When the brains of experimental animals are directly injected with M3G, neuroexcitatory and anti-analgesic responses result, although this does not happen after system administration. Nonetheless, small amounts of M3G do cross the blood–brain barrier, and this may account for some reports of neuroexcitatory responses to morphine in humans. Attempts at correlating M3G plasma concentrations or M3G:morphine or M3G:M6G concentration ratios

Figure 3.6.8 Metabolic pathway of heroin and morphine.

with the clinical activity of M3G have sometimes been successful, and sometimes not. To date, there are only two published studies describing the effects of injecting M3G directly into humans; both studies yielded equivocal results.²⁴

M6G, on the other hand, is pharmacologically active and exerts important clinical opioid effects, especially when it is allowed to accumulate in the plasma of patients who have renal failure. However, after short-term morphine administration, the contribution of M6G to both analgesia and the occurrence of side effects is probably negligible.²⁵ M6G may have peripheral analgesic effects.²⁶ In a placebo-controlled, double blind, crossover study in ten healthy volunteers, M6G was given intravenously as a bolus followed by an infusion sufficient to maintain plasma concentrations of 500 ng/ml for 2 h. Analgesia was produced, but miotic effects were not, suggesting that the pain relief was a consequence of some peripheral effect exerted by M6G.

A small amount of morphine, on the order of 5%, is *N*-demethylated by hepatic CYP3A4, and to a lesser extent CYP2C8, to form normorphine.²⁷ This metabolite itself has pharmacological activity, but it is less potent than morphine and is present in lower concentrations.

3.6.10.2 Heroin

C.R. Wright first synthesized heroin, or 3,6-diacetylmorphine, from morphine in 1874. The Bayer Company of Germany advertised heroin as an antitussive in 1898. Under U.S. law (but not the laws of many other countries) heroin has no accepted medical use; it is classified as a Schedule I drug under the Controlled Substances Act of 1970.

Heroin is typically self-administered by intramuscular or intravenous injection and also by nasal insufflation (“snorting”) or smoking. Peak heroin concentrations in blood are achieved within 1 to 5 min after intravenous and smoked administration²⁰ and within 5 min after intranasal and intramuscular administration.²⁸ In a study in which the method of smoked heroin delivery was optimized to reduce losses due to pyrolysis and sidestream smoke, Jenkins et al.²⁰ reported similar pharmacokinetic profiles for the smoked and intravenous routes. Mean elimination half-lives for two subjects across three doses of heroin were 3.3 and 3.6 min, after smoked and intravenous administration, respectively. The mean residence time of heroin was less than 10 min after all doses by both routes. Cone et al.²⁸ reported that the pharmacokinetic profile of intranasal heroin was equivalent to that for the intramuscular route. Mean elimination half-lives (hours plus or minus SD) were determined to be 0.09 ± 0.05 , 0.07 ± 0.02 , and 0.13 ± 0.07 , following intranasal administration of 6 and 12 mg, and intramuscular administration of 6 mg of heroin, respectively. The relative potency of intranasal heroin was estimated to be approximately one half that of intramuscular administration.

Heroin may also be administered orally. In drug users this is an uncommon route since hydrolysis in the GI tract and loss due to first pass metabolism results in slow and inefficient delivery to the brain. Following low dose administration of 10 mg heroin hydrochloride, no heroin or 6-acetylmorphine was detected in blood.²⁹ Peak morphine concentrations ranging from 2 to 15 ng/ml (mean = 8 ng/ml, $n = 6$) were achieved 7.5 min to 4 h after drug administration. In another study, 400 mg of heroin was orally administered, followed 359 min later by a second dose of 400 mg.³⁰ In this study as well, heroin and 6-acetylmorphine were not detected in blood. Morphine and its conjugates were detected. Peak morphine concentrations were measured 1 to 2 h after the initial dose and were 0.73 and 1.34 mg/L in the two subjects. Girardin et al.³¹ administered heroin by three different routes to eight heroin addicts. The intramuscular route demonstrated linear pharmacokinetics for heroin and the metabolites 6-acetylmorphine (6-AM) and morphine. The oral route resulted in low blood concentrations of heroin and 6-AM but linear kinetics for morphine and its glucuronides.

It is known from *in vitro* studies that heroin is rapidly deacetylated to an active metabolite, 6-AM, which is then hydrolyzed to morphine (Figure 3.6.8). Spontaneous hydrolysis to 6-AM may occur under various conditions. Heroin is susceptible to base-catalyzed hydrolysis but will also hydrolyze in the presence of protic compounds such as ethanol, methanol, and aqueous media.

The addition of two acetyl-ester groups to the morphine molecule produces a more lipophilic compound. Experimental evidence suggests that heroin and morphine may exert their effects via different receptor mechanisms.^{32,33}

Following intravenous infusion of 70 mg of heroin to human volunteers, 45% of the dose was recovered in urine after 40 h. More than 38% was recovered as conjugated morphine, approximately 4% as free morphine, 1% as 6-acetylmorphine, and 0.1% as heroin.¹⁴ Urinary elimination half-lives of 0.6, 4.4, and 7.9 h were reported for 6-AM, morphine, and conjugated morphine, respectively, after administration of 6 mg of heroin by the intramuscular route.³⁴

3.6.10.3 Methadone

Methadone is a synthetic opioid, clinically available in the U.S. since 1947.⁸ It exists in the dextro- and levo-rotatory forms with the levo-isoform possessing approximately 8 to 50 times more pharmacological activity.^{27,34} Methadone acts on the CNS and cardiovascular system producing respiratory and circulatory depression. Methadone also produces miosis and increases the tone of smooth muscle in the lower gastrointestinal tract while decreasing the amplitude of contractions. It is used clinically for the treatment of severe pain and in maintenance programs for morphine and heroin addicts.³⁴

Methadone is typically administered orally, with peak blood concentrations occurring after 4 h. Inturrisi and Verebely³⁵ reported a peak plasma concentration of 75 ng/ml at 4 h after a single 15-mg oral dose. Concentrations declined slowly, with a half-life of 15 h, reaching 30 ng/ml by 24 h. A single 10-mg intravenous dose of methadone resulted in initial plasma concentrations of 500 ng/ml declining to 50 ng/ml after 1 to 2 h.²⁹ Peak plasma concentrations (mean = 830 ng/ml) after 4 h were also observed with chronic oral administration of 100 to 200 mg/day.²⁸ Concentrations of methadone reach a maximum in brain tissue approximately 1 to 2 h after an oral dose.²⁷ Methadone is highly plasma protein bound (87%) with 70% bound to albumin.²⁸ Methadone distributes rapidly to tissues, especially the lungs, liver, kidneys, and spleen. The volume of distribution is 4 to 5 L/kg.³⁴

Methadone is metabolized in the liver by *N*-demethylation to produce unstable metabolites, which undergo cyclization to form the metabolites, 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP) and 2-ethyl-5-methyl-3,3-diphenylpyrroline (EMDP) (Figure 3.6.9). These metabolites and the parent drug undergo para-hydroxylation with subsequent conjugation with glucuronic acid. All three are excreted in the bile and are the major excretory products measured in the urine after methadone administration. Minor metabolites, methadol, and normethadol exhibit pharmacological activity similar to methadone but are produced in low concentrations. Metabolism to EDDP is achieved by multiple cytochrome P450 isoforms, namely, CYP2B6, 2C19, and 3A4.³⁰ Michaelis–Menten data demonstrated that the highest V_{\max} and lowest K_m occurred with CYP2B6. CYP2B6 and 2C19 showed stereoselective metabolism, with the former preferentially metabolizing *S*-methadone and the latter the *R*-enantiomer.³⁰ Shiran et al.³⁶ reported that methadone appears to inhibit CYP2D6 activity.

Large individual variations in the urine excretion of methadone are observed depending on urine volume and pH, the dose and rate of metabolism. Acidification of the urine may increase the urinary output of methadone from 5 to 22%.³⁷ Typically, following a 5-mg oral dose, methadone and EDDP account for 5% of the dose in the 24-h urine. In those individuals on maintenance therapy, methadone may account for 5 to 50% of the dose in the 24-h urine and EDDP may account for 3 to 25% of the dose. (*S*)- and (*R*)-methadone and EDDP have been reported in saliva³⁸ and methadone and (*S*)- and (*R*)-methadone in human breast milk.^{39,40}

3.6.10.4 Oxycodone

Oxycodone is a semisynthetic opioid derived from thebaine and used for oral pain relief. It is commonly formulated as an immediate-release medication with acetaminophen or aspirin. A con-

Figure 3.6.9 Metabolic pathway of methadone.

trolled-release oxycodone formulation is used for the treatment of moderate to severe pain; it provides controlled drug delivery over 12 h. The oral bioavailability of this formulation is 60 to 87%.³⁵ The results of clinical studies of patients with postoperative and cancer pain show that oxycodone has a potency 1.5 times that of morphine.

The absorption half-life of the immediate-release oral formulation is 0.4 h in healthy adults. In contrast the controlled-release form exhibits a biphasic absorption pattern with two apparent half-lives of 0.6 and 6.9 h.⁴¹ Peak plasma concentrations are achieved in approximately 1.6 h with the immediate release compared with 2 to 3 h with the controlled-release formulation. After a 10-mg oral dose of the immediate release formulation, peak plasma concentrations ranged from 13 to 46 ng/ml (mean = 30 ng/ml, $n = 12$).³⁶ After the administration of 20 mg of the prolonged-release formulation the peak plasma concentration averaged 23 ng/ml in a group of 28 adults.⁴¹ The plasma half-life has been reported to be 4 to 6 h with a volume of distribution of 1.8 to 3.7 L/kg.⁴²

Oxycodone is metabolized in the liver by the cytochrome P450 isozymes and the elimination half-life is prolonged in individuals with liver disease, such as cirrhosis. Metabolism by *O*- and *N*-demethylation produces the metabolites oxymorphone and noroxycodone. The *O*-demethylated metabolite, oxymorphone, is a very powerful μ receptor agonist, providing ten times the relief of morphine in patients with cancer,⁴³ and at one time it was believed that most of oxycodone's ability to relieve pain was due to oxymorphone formation. However, recent studies have shown that so little oxymorphone is formed that it cannot account for the relief afforded by the parent compound.^{44–46} Both the *O*- and *N*-demethylated forms are then conjugated with glucuronic acid. CYP2D6 metabolizes oxycodone and is encoded by a polymorphic gene with three mutations (*3, *4, and *5) with a combined 95% allelic frequency and approximately 10% prevalence.⁴⁷ Less than 65% of a single dose is excreted in the urine over a period of 24 h with 13 to 19% comprising free oxycodone.

3.6.10.5 Hydrocodone

Hydrocodone is a semisynthetic opioid derived from codeine.⁸ It is utilized as an analgesic and antitussive available for oral administration, often in combination with acetaminophen or ibuprofen. As a rule, potent analgesics containing a methoxyl group at position 3 (e.g., hydrocodone, $K_i = 19.8$ nM) bind the μ receptor relatively weakly, but their *O*-demethylated metabolites, such as hydromorphone, $K_i = 0.6$ nM, bind more strongly. As with oxycodone, the possibility exists that some of their ability to relieve pain may actually derive from their active metabolites.⁴⁸

Hydrocodone has multiple actions, mainly involving the CNS and smooth muscle. Peak serum concentrations after single therapeutic doses are typically less than 30 ng/ml and occur within 1.5 h after drug administration.²⁵ The plasma half-life has been reported to range from 3.4 to 8.8 h with a volume of distribution of 3.3 to 4.7 L/kg.²⁵ In humans, hydrocodone is metabolized by *O*-demethylation (by the action of CYP2D6) and *N*-demethylation (by the action of CYP3A4) and also reduction of the 6-keto groups. This produces multiple metabolites including hydromorphone, norhydrocodone, hydrocodol, and hydromorphol. The last two metabolites exist as stereoisomers (6- α -hydrocodol is also known as dihydrocodeine). Hydromorphone and hydromorphol are then conjugated to form glucuronides. The unconjugated metabolites are believed to exhibit pharmacological activity and, therefore, may contribute to the actions of the drug. Hydrocodone is principally excreted by the kidneys. Approximately 26% of the drug from a single dose is eliminated in the 72-h urine, with less than 15% as unchanged drug.

3.6.10.6 Fentanyl

Fentanyl is a fast-acting potent synthetic opioid introduced in the U.S. in the early 1960s for use as an anesthetic supplement. It interacts with the opioid mu receptors located in the brain, spinal cord, and smooth muscle. Fentanyl is highly lipophilic and, therefore, crosses the blood–brain barrier rapidly. Therapeutic use involves the CNS, producing pharmacological actions as pain relief and sedation. In addition to its use as an anesthetic agent, fentanyl is prescribed clinically to treat chronic pain. It is available in an oral transmucosal solid formulation and also as a transdermal delivery system (patches). In opioid nontolerant individuals effective analgesia occurs at blood concentrations of 1 to 2 ng/ml.²⁵ Surgical anesthesia occurs at concentrations of 10 to 20 ng/ml.

The transmucosal formulation of fentanyl is designed to be dissolved slowly in the mouth, permitting absorption through the buccal mucosa, and a more prolonged absorption, after swallowing, in the GI tract. Bioavailability is dependent on the fraction of the dose absorbed by both routes. Typically 25% of the dose is rapidly absorbed through the buccal mucosa and approximately 33% of the remaining dose, which is swallowed, becomes systemically available. The time to reach peak blood concentrations after this form of drug delivery is generally 20 to 40 minutes after drug administration.

The transdermal system provides continuous systemic delivery of fentanyl for 72 h. The amount of drug released from the system per hour is proportional to the surface area. Following application of the patch to the skin, a depot of fentanyl concentrates in the upper skin layers. This is then available to the systemic circulation. There is an initial rise in blood fentanyl concentration after application followed by a leveling off that occurs 12 to 24 h later. Peak blood concentrations occur between 24 and 72 h after application. The skin does not appear to metabolize fentanyl when delivered transdermally.

Fentanyl is highly lipophilic. It is rapidly distributed to tissues such as the brain, heart, kidneys, and lungs, followed by slower movement into muscle and fat.

Fentanyl is approximately 80% bound to plasma proteins, principally α -1-acid glycoprotein. The volume of distribution reportedly ranges from 3 to 8 L/kg. The plasma half-life is 3 to 12 h.⁴⁹ Fentanyl is metabolized in the liver and intestinal mucosa by cytochrome P450 3A4 isozyme by *N*-dealkylation to form the pharmacologically inactive metabolite norfentanyl.³⁵ Hydroxylated inactive metabolites include hydroxyfentanyl and hydroxynorfentanyl. Fentanyl is primarily excreted in the urine with up to 85% of a single dose eliminated in 3 to 4 days. Norfentanyl is the principal compound detected in urine comprising 26 to 55% of a single dose.⁵⁰

3.6.10.7 Buprenorphine

Buprenorphine is derived from thebaine. It is a partial mu agonist with kappa antagonist activity. Buprenorphine has 25 to 50 times the potency of morphine. It is used to produce a

longer-lasting analgesia than morphine. Effects of buprenorphine last longer because it is released more slowly from mu receptors than morphine. It is available as an injectable for intramuscular (IM) or intravenous administration in a 1 ml solution containing 0.3 mg buprenorphine (as buprenorphine HCl) for the relief of moderate to severe pain. It is also available to treat opioid dependence in the formulation of a tablet,⁵¹ alone or in combination with naloxone, in 2 or 8 mg doses to be administered sublingually (SL).²⁵ The recommended sublingual daily dose is 12 to 16 mg/day.

Pharmacological effects occur within 15 min of IM administration, peaking at approximately 1 h and persisting for up to 6 h. After SL administration, peak pharmacological effects typically occur after 100 min. After an intravenous dose of 0.3 mg, plasma concentrations are typically less than 1 ng/ml. Sublingual maintenance therapy of 8 mg/day resulted in plasma buprenorphine concentrations of 1 to 8 ng/ml.⁵²

The bioavailability of the buprenorphine/naloxone tablet appears to be greater than the buprenorphine-alone formulation, with the former similar to the drug in liquid form. Buprenorphine is approximately 96% plasma protein bound, primarily to α - and β -globulin. The plasma half-life is 2 to 4 h with a volume of distribution of 2.5 L/kg. The drug undergoes *N*-dealkylation by CYP3A4 isozyme to norbuprenorphine, a pharmacologically active metabolite. This metabolite and parent are subject to glucuronidation. Buprenorphine is eliminated primarily in the feces as free drug with low concentrations occurring in the urine.

3.6.10.8 Tramadol

Tramadol has about one tenth the pain-relieving ability of morphine.⁵³ There are two enantiomers, and both contribute to pain relief, but via different mechanisms. (+)-Tramadol and the metabolite (+)-*O*-desmethyl-tramadol, which is referred to as M1, are agonists of the mu opioid receptor. (+)-Tramadol inhibits serotonin reuptake and (–)-tramadol inhibits norepinephrine reuptake.²⁵ This latter action enhances the inhibitory effects on pain transmission in the spinal cord. Because the actions of the two enantiomers are complementary, they are usually supplied as a racemic mixture. However, because it is a serotonin-reuptake blocker, interaction with other medications can lead to the occurrence of serotonin syndrome.⁵⁴

Tramadol is available as drops, capsules, and sustained-release formulations for oral use, suppositories for rectal use, and solution for intramuscular, intravenous, and subcutaneous injection. After oral administration, tramadol is rapidly and almost completely absorbed. Sustained-release tablets release the active ingredient over a period of 12 h, reach peak concentrations after 4.9 h and have a bioavailability of 87 to 95% compared with capsules. One 100-mg dose given to healthy volunteers resulted in plasma levels of 375 ng/ml at 1.5 h.⁵⁵ Tramadol is 20% bound to plasma protein and it is rapidly distributed in the body; it is mainly metabolized by *O*- and *N*-demethylation forming glucuronides and sulfates that are excreted by the kidney.

The mean elimination half-life is about 6 h. The *O*-demethylation of tramadol to M1, the main analgesic effective metabolite, is catalyzed by cytochrome P450 (CYP) 2D6, whereas *N*-demethylation to M2 is catalyzed by CYP2B6 and CYP3A4. The wide variability in the pharmacokinetic properties of tramadol can partly be ascribed to CYP polymorphism. *O*- and *N*-demethylation of tramadol as well as renal elimination are stereoselective.⁵⁶

Pharmacokinetic–pharmacodynamic characterization of tramadol is difficult because of differences between tramadol concentrations in plasma and at the site of action, and because of pharmacodynamic interactions between the two enantiomers of tramadol and its active metabolites.⁵³

3.6.10.9 Hydromorphone

Sold as Dilaudid™ in the U.S., hydromorphone is a semisynthetic, differing from morphine only by presence of a 6-keto group, and the hydrogenation of the double bond at the 7–8 position

of the molecule.⁵⁷ Like morphine, it acts primarily at the mu opioid receptors, and to a lesser degree at delta receptors.

As a hydrogenated ketone of morphine, it shares common pharmacologic properties with other opioid analgesics.²⁵ These include the expected changes in the CNS, including increased cerebrospinal fluid pressure, increased biliary pressure, and increased parasympathetic activity. It can also produce transient hyperglycemia. It is generally viewed as a second tier analgesic and is not that widely prescribed.

Hydromorphone is well absorbed from the small intestine and is extensively metabolized in the liver, mainly to 3-glucuronide which, like morphine, is devoid of analgesic effect, but can cause significant neuroexcitation. It undergoes extensive first pass metabolism (62%), accounting for its relatively low bioavailability. A single 8-mg dose of hydromorphone yields blood concentrations of approximately 2 ng/ml, while a 12-mg time-release formulation gives plasma concentrations half as high.^{58,59}

Depending on the country where the drug is manufactured, a number of different time-release preparations are available. Palladone™, a controlled-release preparation consisting of hydromorphone HCl pellets, was withdrawn from the U.S. market in 2005. When taken with alcohol the pellets rapidly released their contents leading to dangerously elevated peak plasma concentrations.⁶⁰ Interaction with ethanol and “dose dumping” is not the only concern. Any CNS depressant may enhance the depressant effects of hydromorphone.

3.6.11 Phencyclidine

Phencyclidine, PCP, or 1-(1-phenylcyclohexyl) piperidine, is an arylcyclohexamine with structural similarities to ketamine. It is a lipophilic weak base with a pKa of 8.5. Phencyclidine was originally synthesized and marketed under the trade name Sernyl[®], by Parke-Davis for use as an intravenously administered anesthetic agent in humans. Distribution began in 1963 but was discontinued in 1965 due to a high incidence (10 to 20%) of post-operative delirium and psychoses. However, its use continued as a veterinary tranquilizer for large animals until 1978, when all

manufacture was prohibited and PCP was placed in Schedule II of the federal Controlled Substances Act (1970).

Illicit use of PCP as a hallucinogenic agent was first reported in San Francisco in 1967.¹ It was first abused in oral form but then gained popularity in the smoked form as this mode of drug delivery allowed better control over dose. Because illicit synthesis is relatively easy and inexpensive, abuse became widespread in the 1970s and early 1980s. Today, use of PCP tends to be highly regionalized and located in certain areas of the U.S., notably the Washington D.C./Baltimore corridor, New York City, and Los Angeles.²

3.6.11.1 Pharmacology

Phencyclidine binds with high affinity to sites located in the cortex and limbic structures of the brain. Binding results in blockade of *N*-methyl-D-aspartic acid (NMDA)-type glutamate receptors. The actions of glutamate and aspartate at the NMDA receptor allow movement of cations across the cell membrane. PCP exerts its action by binding to the glutamate receptor, thus preventing the flux of cations.³ PCP is also known to exert effects on catecholamines, serotonin, gamma-hydroxy butyric acid, and acetylcholine neurotransmitter release, but its role is incompletely defined. Due to its action on several systems, the physiological and behavioral effects of PCP are varied and depend on not only the dose, but also the route of administration and user's previous experience.

3.6.11.2 Absorption

Phencyclidine is typically self-administered by the oral, intravenous, or smoked routes. After oral administration to healthy human volunteers, the bioavailability was found to vary between 50 to 90%.⁴ In this study, peak plasma concentrations were achieved after 1.5 h and appeared to correlate with the time to reach maximum pharmacological effects. However, because there have been no comprehensive clinical controlled studies of phencyclidine, a correlation between PCP blood concentrations and pharmacological effects has not been definitively documented. Maximum serum PCP concentrations ranged between 2.7 and 2.9 ng/ml after 1 mg PCP administered orally.⁴

PCP is commonly self-administered by the smoked route. Liquid PCP is soaked in parsley flakes and rolled as a cigarette; powdered PCP is sprinkled over a marijuana joint, or the end of a tobacco cigarette is dipped in liquid PCP and then smoked. Cook et al.⁵ studied the pharmacokinetic properties of PCP deposited on parsley cigarettes. Upon smoking, PCP is partially volatilized to 1-phenylcyclohexene (PC). These investigators found that $69 \pm 5\%$ of the PCP available in the cigarette was inhaled, 39% as PCP and 30% as PC.⁵ The pharmacological and toxicological properties of PC have not been established. Peak plasma concentrations of PCP were reached within 5 to 20 min. In 80% of the subjects, a second peak was observed in plasma PCP concentrations, occurring 1 to 3 h after the end of smoking. This may have been due to trapping of PCP in the mouth, where it could be released and absorbed by the GI tract or, alternatively, it could be due to absorption by the lung and bronchial tissue with slower release into the systemic circulation.⁶ Long-term users of PCP report feeling the effects of the drug within 2 to 5 min of smoking, with a peak effect after 15 to 30 min and residual effects for 4 to 6 h.⁷

3.6.11.3 Distribution

Plasma protein binding of PCP in healthy individuals remains relatively constant between 60 to 70% over the concentration range of 0.007 to 5000 ng/ml.⁵ PCP binding to serum albumin accounts for only 24% of the binding,⁶ which suggests binding to another protein may occur to a significant extent. When studied *in vitro*, α_1 -acid glycoprotein was also found to bind phencyclidine.⁶ The volume of distribution has been shown to be large, between 5.3 and 7.5 L/kg,⁸ providing evidence of extensive distribution to extravascular tissues.

Wall et al.⁹ administered 1.3 µg/kg of 3H-PCP intravenously to human volunteers and collected blood samples for 72 h. Data from this study suggested a two-compartment pharmacokinetic model with a plasma half-life for PCP of 7 to 16 h. Domino et al.¹⁰ further analyzed the data from Wall et al. and developed a more complex three-compartment PK model. The reported half-lives for each compartment were 5.5 min, 4.6 h, and 22 h. The specific tissues and organs represented by the multicompartment model were not identified. Half-lives of greater than 3 days have been reported in cases of PCP overdose.¹¹

3.6.11.4 Metabolism and Excretion

PCP is metabolized by the liver through oxidative hydroxylation. Unchanged PCP, two monohydroxylated, and one dihydroxylated metabolite have been identified in urine after oral and intravenous administration.¹² The monohydroxylated metabolites have been identified as 4-phenyl-4-(1-piperidinyl)-cyclohexanol (PPC) and 1-(1-phenylcyclohexyl)-4-hydroxypiperidine (PCHP). These metabolites are pharmacologically inactive in humans and PPC is present in both *cis*- and *trans*-isomeric forms. The *cis/trans* ratio was found to be 1:1.4 in human urine.⁵ The dihydroxylated metabolite was identified as 4-(4-hydroxypiperidino)-4-phenylcyclohexanol (HPPC). These metabolites are present in urine as glucuronide conjugates in addition to their unconjugated forms.⁸

Approximately 30 to 50% of a labeled intravenous dose is excreted over a 72-h period in urine as unchanged drug (19.4%) and 80.6% as polar metabolites, mainly 4-phenyl-4-(1-piperidinyl) cyclohexanol.⁵ Only 2% of a dose is excreted in feces.¹⁰ After 10 days, an average of 77% of an intravenous dose is found in the feces and urine.⁹ Green et al.¹² reported urine PCP concentrations between 40 to 3400 ng/ml in ambulatory users.

Urine pH is an important determinant of renal elimination of PCP. In a study in which urine pH was uncontrolled (6.0 to 7.5), the average total clearance of PCP was 22.8 ± 4.8 L/h after intravenous administration.⁴ In the same study, renal clearance was 1.98 ± 0.48 L/h. When the urine was made alkaline, the renal clearance of PCP was found to decrease to 0.3 ± 0.18 L/h. If the urine was acidified (pH 6.1) in the same subjects, renal clearance increased to 2.4 ± 0.78 L/h.¹³ Aronow et al.¹⁴ determined that if the urine pH was decreased to <5.0, renal clearance increased significantly to 8.04 ± 1.56 L/h. There is disagreement about the utility of urine acidification in the treatment of PCP overdose, even though excretion may be increased by as much as 100-fold.¹⁵ It should be noted that acidification may increase the risk of metabolic complications.¹⁶

3.6.12 Ketamine

Ketamine, a weakly basic compound structurally and pharmacologically similar to phencyclidine, is utilized in the U.S. to induce anesthesia.¹ It is available in solution for intravenous or intramuscular injection. Since the drug is pharmacologically similar to PCP it has the potential of producing hallucinogenic effects and, therefore, in recent years has become a drug of abuse.

After intravenous administration of 175 mg/70 kg to five individuals, the average peak serum concentration was 1.0 mg/L achieved at 12 min.² The concentration declined by 50% within 30 min. The plasma half-life is reported to be 3 to 4 h with a volume of distribution of 3 to 5 L/kg.¹ Continuous infusion of 41 µg/kg/min after a 2 mg/kg bolus produced an average ($n = 31$) steady-state plasma concentration of 2.2 mg/L.³

Two metabolites are formed that achieve serum concentrations similar to ketamine and may also exhibit the depressant effects of the parent compound. Norketamine is produced by *N*-demethylation.⁴ Norketamine is then dehydrogenated to form dehydronorketamine. Parent drug and metabolites are then subject to hydroxylation and conjugation. Approximately 2% of a single dose of ketamine is excreted in the 72-h urine as unchanged drug. In a recent study urine ketamine concentrations ranged from 6 to 7744 ng/ml (mean = 1083 ng/ml) in 33 subjects following illegal consumption.⁵

INTRODUCTION

Pharmacodynamics is the study of the physiological and behavioral mechanisms by which a drug exerts its effects in living organisms. An effect is initiated by the drug binding to receptor sites in a cell's membrane, setting in motion a series of molecular and cellular reactions culminating in some physiological (e.g., opioid-induced analgesia) or behavioral (e.g., alcohol-induced impairment) effect. Drugs typically have multiple effects. For example, a benzodiazepine will produce its primary anxiolytic effect, but may also cause side effects of sedation and impaired performance.

Central to an understanding of drug abuse and its treatment is a complete knowledge of the pharmacodynamics of psychoactive drugs. The question of the behavioral effects of abused drugs has been the focus of research by behavioral pharmacologists for many decades. In this section, we focus on the performance effects of drugs of abuse and the abuse of several marketed drugs. Because of the widespread use of psychoactive drugs throughout society, employers have become increasingly concerned about drugs in the workplace and the potential for impaired job performance and onsite drug-related accidents. There are now computerized tests that employers can use to aid in the detection of impaired employees. Some drugs of abuse also produce characteristic effects on the visual system, and for this reason, devices that detect eye movement and function are also being tested for their ability to predict drug ingestion and potential impairment in the workplace.

4.1 EFFECTS OF ABUSED DRUGS ON HUMAN PERFORMANCE: LABORATORY ASSESSMENT

Stephen J. Heishman, Ph.D. and Carol S. Myers, Ph.D.

Clinical Pharmacology and Therapeutics Branch, National Institute on Drug Abuse, National Institutes of Health, Department of Health and Human Services, Baltimore, Maryland

4.1.1 Introduction

The experimental investigation of the effects of psychoactive drugs on human performance has enjoyed a long history. Some of the earliest university laboratories in departments of psychology and physiology were dedicated to the study of caffeine, nicotine, and other drugs.^{1,2} Advances in technology and methodology have resulted in a comprehensive body of research, and for most drugs of abuse, we have a general idea of their effects on performance. For example, it is well known that psychomotor stimulants, such as D-amphetamine, increase one's ability to sustain attention over prolonged periods of time when performing monotonous tasks.^{3,4} However, numerous inconsistencies exist in the literature concerning the effects of certain drugs on various aspects of human performance, and few studies take into account nonpharmacological variables that, in addition to the drug dose, ultimately determine behavioral effects of psychoactive drugs.^{5,6}

The purpose of this chapter is to provide an overview of the effects of abused drugs on human performance as assessed in the laboratory. This is not an exhaustive review of the literature. Rather, we take as our starting point several general overviews⁷⁻⁹ and drug-specific reviews^{3,4,6,10-18} and update these findings with recent studies. The classes of drugs included in this review are (1) psychomotor stimulants, including D-amphetamine, cocaine, and 3,4-methylenedioxymethamphetamine (MDMA, ecstasy); (2) nicotine and tobacco; (3) sedative-hypnotics, focusing on benzodiazepines as the prototypical sedative-hypnotic in use today (effects of ethanol are discussed elsewhere in this volume); (4) opioid analgesics and anesthetics; and (5) marijuana. Within each drug category, results will be organized into sensory, motor, attentional, and cognitive abilities. Such a classification scheme allows a focus on behavior compared with, for example, a classification based on specific performance tests.

4.1.2 Psychomotor Stimulants

4.1.2.1 Cocaine and D-Amphetamine

The psychomotor stimulants, cocaine and D-amphetamine, are considered together because they share a similar psychopharmacological profile.^{19,20} Low to moderate doses of both drugs given acutely to nontolerant, nonanxious subjects produce increases in positive mood (euphoria), energy, and alertness. Experienced cocaine users were unable to distinguish between intravenous (IV) cocaine and D-amphetamine,²¹ and cross-tolerance between cocaine and D-amphetamine with respect to their anorectic effect has been demonstrated.²² Additionally, the toxic psychosis observed after days or weeks of continued use of both psychostimulants is very similar. The fully developed toxic syndrome, characterized by vivid auditory and visual hallucinations, paranoid delusions, and disordered thinking, is often indistinguishable from paranoid schizophrenia.²⁰ Derlet et al.²³ reported that the most prominent presenting symptoms seen in 127 cases of amphetamine toxicity were agitation, suicidal ideation, hallucinations, delusions, confusion, and chest pain. Once drug use ceases, symptoms usually resolve within 1 week.

Research studies on human performance have typically involved the administration of cocaine and D-amphetamine in single doses that do not produce toxic psychosis. In the studies reviewed, D-amphetamine was administered orally (PO). Given that the performance effects of D-amphetamine have been studied for more than 60 years and its widespread use during World War II,²⁴ it is not surprising that much is known about the effects of D-amphetamine on vigilance and attention. However, the effect of psychostimulants on higher-order cognitive processes has not been widely studied.

Sensory Abilities

A frequently used measure of central nervous system (CNS) functioning is critical flicker frequency (CFF) threshold. The task requires subjects to view a light stimulus and to note the point (frequency) at which the steady light begins to flicker (or vice versa), as the experimenter changes the frequency of the light. An increase in CFF threshold indicates increased cortical and behavioral arousal, whereas a decrease suggests lowered CNS arousal.²⁵ D-Amphetamine reliably increases CFF threshold.^{8,25} In the only study, to our knowledge, intranasal cocaine (100 mg) had no effect on CFF threshold.²⁶

Motor Abilities

Finger tapping is considered to be a measure of relatively pure motor activity. One study found that D-amphetamine (10 mg) produced a 5% increase in tapping rate,²⁷ whereas three other studies reported no effect.²⁸⁻³⁰ The circular lights test is a measure of gross motor coordination in which subjects extinguish lights by pressing buttons that are arranged in a 72-cm-diameter circle on a

wall-mounted panel. The test is typically performed for 1 min. D-Amphetamine (25 mg) increased response rate on the circular lights test in one study,³¹ but another study reported no effect of 20 mg D-amphetamine.³² The effect of cocaine on finger tapping and circular lights performance has not been examined.

Attentional Abilities

Attention is a broad psychological category encompassing behaviors such as searching, scanning, and detecting visual and auditory stimuli for brief or long periods of time.^{33,34} In nearly all performance tests assessing attention, responding is measured in some temporal form, such as reaction or response time, time off target, or response rate. If appropriate, response accuracy is also reported. Because of differential drug effects, it can be helpful to distinguish among focused, selective, divided, and sustained attention.⁶

Focused attention involves attending to one task for a brief period of time, usually about 5 min or less. In this regard, D-amphetamine⁷ and cocaine²⁶ have been shown to improve performance in auditory and visual reaction time tests, although other studies have reported no effect of D-amphetamine. A brief, frequently used test of psychomotor skills and attention is the digit symbol substitution test (DSST), which originated as a paper and pencil subtest of the Wechsler Adult Intelligence Scale and now exists in a computerized version.³⁵ The DSST requires subjects to draw the symbol or type the pattern associated with each numeral 1 to 9. The number of attempted and correct symbols or patterns during the 90-s test is recorded. In general, D-amphetamine^{7,36} and cocaine^{37–39} enhanced performance on the DSST, although Foltin et al.⁴⁰ reported that cocaine decreased number of attempted trials, and others have reported no effect of smoked cocaine⁴¹ or D-amphetamine.^{42,43}

A few recent studies have looked at behavioral inhibition using reaction time tasks that require the participant to make quick responses to “go” signals and inhibit responding to “stop” signals. An impairment in the ability to inhibit responses is used as a measure of impulsivity. Cocaine administered orally to cocaine users dose-dependently impaired the ability to inhibit responses.⁴⁴ However, in another study in which cocaine was smoked, there was no effect on reaction time.⁴¹ In contrast, D-amphetamine administered orally to healthy volunteers improved inhibition, but only in those people who had slow baseline stop responses.⁴⁵

Examining selective attention, two studies reported that D-amphetamine improved accuracy,^{46,47} and either increased⁴⁶ or decreased⁴⁷ reaction time. The effect of D-amphetamine and cocaine on divided attention has not been widely investigated; two studies reported small increases in accuracy on a divided attention test after administration of D-amphetamine.^{48,49} Several studies have shown that D-amphetamine reliably enhanced performance in tests of visual and auditory vigilance.^{7,50} The time of effect in these studies was 1 to 4 h after drug administration, suggesting that D-amphetamine improved performance by preventing the vigilance decrement that typically occurs in tests of sustained attention.

Cognitive Abilities

Psychostimulants have produced inconsistent effects on tests of cognition. Several studies have investigated the effect of cocaine on a test of repeated acquisition and performance of response sequences. In the acquisition component, subjects attempt to learn by trial and error a predetermined sequence of 10 numbers within 20 trials. Subjects learn a new sequence each time they perform the test. In the performance component, the response sequence remains constant throughout the experiment, and thus subjects repeat an already learned sequence. Two studies have reported no effect of either intranasal (IN) or IV cocaine on the test.^{37,40} However, Higgins et al.⁵¹ reported that cocaine (96 mg, IN) decreased response rate during the acquisition phase and increased response accuracy during the performance component. In a similar serial acquisition procedure, cocaine has been shown to have no effect.^{52,53}

Cocaine²⁶ and D-amphetamine⁷ had no effect on simple arithmetic skills. With respect to memory, most studies have also indicated no effect of D-amphetamine on immediate recall of lists of numbers.⁷ However, Soetens et al.⁵⁴ reported that D-amphetamine (10 mg) administered PO before learning and intramuscularly (IM) after learning enhanced recall of a word list for up to 3 days. D-Amphetamine also enhanced performance on a working memory task, but only in subjects with a low baseline working memory capacity. In contrast, amphetamine diminished performance in high-baseline subjects.⁵⁵

Summary

The performance effects of D-amphetamine have been studied to a greater extent than those of cocaine; however, because of their similar pharmacology, both drugs generally produce comparable effects. Psychostimulants in low to moderate doses typically produce behavioral and cortical arousal, and thus D-amphetamine reliably increases CFF threshold and has been shown in some studies to increase finger tapping rate and gross motor coordination. A relatively large body of literature indicates that D-amphetamine and cocaine enhance attentional abilities, including brief tests requiring focused attention and vigilance tasks requiring sustained attention. The majority of studies have shown that cocaine and D-amphetamine have no effect on learning, memory, and other cognitive processes, such as solving arithmetic problems.

4.1.2.2 3,4-Methylenedioxymethamphetamine (MDMA; Ecstasy)

Since the late 1980s, MDMA (ecstasy) has become an increasingly popular recreational drug among teenagers and young adults. MDMA has structural similarities to hallucinogens and psychomotor stimulants and acts to release presynaptic monoamines, primarily serotonin. Cardiovascular effects are similar to other stimulants and include increases in heart rate and blood pressure due to peripheral norepinephrine release. Users report a sense of well-being, heightened responsiveness to emotions, and feelings of intimacy toward other people. These effects are sometimes accompanied by mild hallucinations and perceptual disturbances, thought to be due to the drug's interaction with postsynaptic 5-HT₂ receptors.⁵⁶ There have been reports of MDMA-generated psychotic syndrome, anxiety-related disorders, and other psychiatric symptoms.

MDMA is most often taken orally in a typical dose range per tablet of 50 to 100 mg.^{57,58} Neurotoxicity of MDMA to serotonergic systems has been demonstrated in animal studies; therefore for ethical reasons most research has been accomplished using light to heavy MDMA users. Methodological confounds associated with this include the sometimes extensive previous or concurrent use of other drugs, the existence of premorbid psychiatric syndromes often is not explored or reported, and variability in the components of street drugs sold as "ecstasy."

Sensorimotor Abilities

Prepulse inhibition (PPI) of acoustic startle is the reduction of a startle response to a stimulus when that stimulus is preceded by a weaker stimulus. PPI has been used as an operational measure to study sensorimotor gating in a variety of populations. In a double-blind, placebo-controlled study, MDMA (1.7 mg) was administered orally to healthy, non-MDMA-using volunteers to determine the effect on PPI. MDMA produced a slight but significant increase in startle reactivity.⁵⁹ Using a trail-making test to assess psychomotor speed, there were no differences in performance between current and former MDMA users, polydrug users, and drug naïve participants.⁶⁰ Similarly, users of MDMA were asked to perform a simple reaction time task after administration of 75 and 125 mg of MDMA and neither dose affected task performance.⁶¹

Attentional Abilities

There are several reports of decrements in attentional processes among MDMA users. Focused attention, as assessed by the DSST, was significantly worse among MDMA users who were administered 125 mg MDMA.⁶¹ In another study employing a similar task, MDMA users who were abstinent for 3 weeks prior to testing were significantly less accurate than non-MDMA users at baseline.⁶² On a divided attention task requiring attention to simultaneously presented visual and auditory cues, participants who were regular users of both cannabis and MDMA performed more poorly than cannabis users only and than participants who used neither drug. These MDMA/cannabis users also performed more poorly than either comparison group on a selective attention task requiring visual memory, target selection, and response inhibition.⁶³ Adolescent MDMA users performed significantly worse as compared to drug naïve adolescents on both selective and divided attention tasks.⁶⁴ However, another group reported no impairment in divided attention in either current or former MDMA users.⁶⁰

Reports of sustained attention performance are mixed. In studies that used the Continuous Performance Task (CPT), no differences were observed between MDMA users and drug naïve controls.^{64,65} Using a visual search scan, regular (>10 times) and novice (≤10 times) users of MDMA were compared to MDMA naïve participants. Subjects were tested off-drug, when the user groups were actively self-administering MDMA, and at three times (up to 7 days) after the last drug use. Visual scanning was impaired only when the user groups were on MDMA.⁶⁶ This was confirmed in a second study in which these groups were tested only while they were drug-free, and there were no differences in sustained attention performance between the three groups.⁶⁷ In contrast is a report of MDMA users who were abstinent for 3 weeks prior to testing, yet still had performance decrements on a sustained attention task that required arithmetic calculations.⁶²

Cognitive Abilities

Many studies that have assessed cognitive processes have demonstrated impairment in both active and abstinent users of MDMA, particularly on memory performance. Memory decrements have been reported long after users had ceased taking the drug. For example, immediate⁶⁷ and delayed recall was significantly worse in novice⁶⁶ and regular MDMA users,^{66–68} compared to MDMA-naïve participants, whether they were on or off drug.^{66,67} Memory scores remained poor in the regular MDMA users up to 7 days after drug use.⁶⁶ Other studies have confirmed that memory difficulties can persist after drug use has ended. MDMA users who were abstinent 1 week,⁶⁹ 3 weeks,⁶² 2 months,⁷⁰ 6 months,^{68,71} and at least 1 year⁷⁰ showed impaired performances on short-term memory,^{62,69–71} delayed recall,^{68,70} working memory,^{62,71} and logical reasoning⁶² compared to MDMA-naïve control groups. However, another study found no decrements in working memory in MDMA users,⁶⁰ and Parrott¹⁸ mentioned several unpublished reports in which unimpaired learning or memory task performance was observed in users.

One problem, as noted earlier, is that cognitive deficits reported in these studies might be confounded by concurrent use of other drugs. For example, one investigator⁷² reported that it was impossible to recruit MDMA users who did not also use cannabis. Exploring the relationship of these two drugs, one group reported that cannabis-only users and drug-naïve participants performed significantly better on tests of working memory, immediate recall, selective and divided attention, and logical thinking compared to users of MDMA + cannabis.⁶³ In that group, the use of cannabis was related to more pronounced cognitive deficits. In contrast, other investigators have reported that both drug-using groups each performed significantly worse than non-users on several measures of memory and other cognitive processes,^{72,73} suggesting that coincident cannabis use might account for the cognitive impairment in MDMA users. However, in one of those studies⁷² the MDMA + cannabis group did perform worse on two delayed recall tasks and others also have reported similar findings on various cognitive tasks.^{17,18,57,58}

Summary

Simple cognitive processes such as reaction time seem to be normal among MDMA users, with the exception of one report of altered sensorimotor gating. More complex cognitive processes, such as attentional processes, appear to be more susceptible to disruption by MDMA. Although the literature is mixed, the use of MDMA has been reported to disrupt focused, divided, selective, and sustained attention. There is a growing body of evidence that even light recreational use of MDMA can have long-lasting effects on memory, including verbal and visual recall and working memory. The degree of memory impairment is associated with the extent and intensity of drug use and might be enhanced by concurrent cannabis use, and memory deficits can be long lasting.

4.1.3 Nicotine and Tobacco

The vast majority of people who use nicotine (either cigarettes or smokeless tobacco products) use the drug on a daily basis and are considered to be addicted to or dependent on nicotine. In contrast, a minority of people who use the other psychoactive drugs considered in this chapter for nonmedical purposes develop a drug dependence. Daily smokers accumulate plasma levels of nicotine that increase during the day, decline overnight, but never reach zero. This poses a unique problem when conducting behavioral studies with smokers. When improvements in performance are observed after nicotine is given to smokers who have been tobacco-deprived overnight (a common design strategy), it is impossible to determine whether such improvements represent a true enhancement of performance or the alleviation of withdrawal-induced performance deficits. The latter explanation would simply represent a reversal to the person's normal smoking behavioral baseline, not a true enhancement above baseline performance. Unlike other drugs of abuse that are typically tested in nondependent, nontolerant subjects, this issue must always be considered when interpreting the effects of nicotine on smokers' performance.

Two papers have thoroughly reviewed the literature on the effects of nicotine and cigarette smoking on human performance.^{6,15} In general, both reviews concluded that nicotine does not universally enhance performance and cognition and that any nicotine-induced performance improvements are small in magnitude. Heishman et al.⁶ suggested that the limited performance-enhancing effects of nicotine are not likely to be an important factor in the initiation of cigarette smoking by adolescents (the modal age for starting tobacco use is between 11 and 15; beginning after high school is rare⁷⁴). However, once an individual is dependent on nicotine, data suggest that nicotine deprivation maintains smoking, at least in part, because nicotine can reverse withdrawal-induced performance decrements.⁶

Because the majority of studies in this area are methodologically deficient, only studies that used placebo-control conditions and single- or double-blind drug administration procedures are included in this section. Additionally, because of the problem of interpreting nicotine-induced changes in smokers' performance as discussed above, a distinction will be made between studies that administered nicotine to subjects under conditions of nicotine deprivation and no deprivation. Studies involving no nicotine deprivation include nondeprived smokers and nonsmokers.

4.1.3.1 Sensory Abilities

Sherwood et al.⁷⁵ administered nicotine polacrilex gum (0 and 2 mg) three times at 1-h intervals to smokers who were overnight deprived and measured CFF after each administration. CFF threshold was increased over predose baseline after the first 2-mg dose, but no further increase after the second and third doses was observed. Thus, the initial dose appeared to reverse a deprivation-induced deficit, and subsequent doses maintained normal functioning. Baseline CFF was not measured before subjects were tobacco abstinent. No effect of nicotine on CFF was reported following administration of nicotine polacrilex or subcutaneous (SC) nicotine injections

to 24-h abstinent smokers, nonabstinent smokers, and nonsmokers.^{76–79} The lack of effect of nicotine in the absence of nicotine deprivation is consistent with the data of Sherwood et al.,⁷⁵ further suggesting that nicotine reverses withdrawal-induced deficits, but does not produce true enhancement of CFF threshold.

4.1.3.2 Motor Abilities

Perkins et al.⁸⁰ administered placebo and nicotine nasal spray (15 µg/kg) to smokers who were tobacco deprived for at least 12 h. Nicotine reliably increased finger tapping rate in all subjects, and produced a nonsignificant trend toward improved hand steadiness. In a subsequent study, Perkins et al.⁸¹ reported that nicotine (5, 10, and 20 µg/kg) increased finger tapping rate, but impaired hand steadiness and hand tremor in nonsmokers and overnight tobacco abstinent smokers. Finger tapping rate was also increased by nicotine in nonsmokers who were administered nicotine nasal solution or spray^{80,82} or SC nicotine injections.⁷⁷ In contrast, Foulds et al.⁷⁹ found that nicotine injections (0.3 and 0.6 mg, SC) had no effect on finger tapping rate in nonsmokers, and only 0.3 mg nicotine produced a slight tapping rate increase in 24-h abstinent smokers. Heishman and Henningfield⁸³ administered nicotine polacrilex gum (0, 2, 4, 8 mg) to nonsmokers each day for 8 days and found that the 8-mg dose impaired gross motor performance on the circular lights test.

4.1.3.3 Attentional Abilities

Numerous studies investigating focused attention have used reaction time tests. Nicotine polacrilex gum (2 mg) produced faster motor reaction time, but did not affect recognition reaction time in overnight deprived smokers,⁷⁵ nonabstinent smokers,⁷⁶ and a group of nonabstinent smokers and nonsmokers.⁷⁸ Le Houezec et al.⁸⁴ found that SC nicotine (0.8 mg) increased the number of fast reaction times, but did not affect task accuracy. Griesar et al.⁸⁵ reported faster reaction time following administration of transdermal nicotine patch compared to placebo patch in nonsmokers. However, Hindmarch et al.⁷⁶ reported no effect of 2-mg polacrilex on reaction time in nonsmokers.

Selective attention can be defined as the ability to attend to a target stimulus while simultaneously ignoring irrelevant or distracting stimuli. In 12-h tobacco-deprived smokers, nicotine polacrilex (2 and 4 mg) reversed deprivation-induced impairments in letter searching to pre-deprivation baseline⁸⁶ and had no effect on Stroop and letter cancellation tests.⁸⁷ The Stroop test compares the time required for subjects to name the ink color of color words that are incongruent (e.g., the word red printed in blue ink) vs. the ink color of neutral stimuli, such as non-color words or colored squares. Typically, the incongruent task takes more time than the neutral stimulus task because the tendency to read the color word interferes with naming its ink color; the difference in time between the two tasks is considered a measure of selective attention or distractibility.⁸⁸ In two studies comparing abstinent smokers and nonsmokers on the Stroop test, nicotine nasal spray (5, 10, and 20 µg/kg) improved response time, but impaired accuracy with regard to the Stroop conflict,⁸¹ whereas nicotine injections (0.3 and 0.6 mg, SC) had no effect.⁷⁹ Using the Stroop test with nonsmokers, Wesnes and Revell⁸⁹ found no effect of 1.5-mg nicotine tablets, whereas Provost and Woodward⁹⁰ reported faster response time after 2-mg nicotine polacrilex. In two studies with nonsmokers, nicotine polacrilex (2 and 4 mg) had no effect on letter searching response time or accuracy,⁹¹ whereas 8-mg polacrilex impaired letter searching accuracy.⁸³

Using a divided attention test that required subjects to perform simultaneously a central tracking task and respond to peripheral visual stimuli, Sherwood et al.⁷⁵ found that 2-mg polacrilex decreased tracking errors, but had no effect on reaction time to the peripheral lights in overnight deprived smokers. There were fewer tracking errors after the third nicotine dose compared to the first dose, and placebo responding was unchanged, suggesting a true enhancement of performance. In the same divided attention test, nicotine decreased errors on the tracking task in nonabstinent smokers^{76,78} but had no effect in nonsmokers.⁷⁶

The rapid visual information processing (RVIP) test has been used in numerous studies investigating the effects of smoking and nicotine on sustained attention. This test requires subjects to press a button when they detect three consecutive even or odd digits in a series of single digits presented on a video monitor at 600-ms intervals. In tobacco-deprived smokers, RVIP accuracy was improved after subjects smoked cigarettes,⁹² were administered nicotine polacrilex,^{87,93} or received SC injections of nicotine.⁷⁹ However, there was no effect on RVIP performance in smokers who were abstinent for 2 h and given polacrilex (4 mg)⁹⁴ and in nondeprived smokers allowed to smoke one cigarette.⁹⁵ Wesnes et al.⁹⁶ reported that the decline in signal detection during an 80-min vigilance test was less after active nicotine tablets compared with placebo in 12-h deprived smokers. Testing nonsmokers, three studies reported that nicotine had no effect on the RVIP test compared to placebo conditions,^{77,97,98} whereas Foulds et al.⁷⁹ reported faster reaction time after nicotine injections (0.3 and 0.6 mg, SC). Levin et al.⁹⁹ found that transdermal nicotine decreased errors of omission on a continuous performance test in nonsmokers. Nonsmokers were also administered nicotine tablets in the Wesnes et al.⁹⁶ study, and no difference between abstinent smokers and nonsmokers was observed, suggesting that nicotine functioned to reverse deprivation-induced deficits in the 12-h abstinent smokers.

4.1.3.4 Cognitive Abilities

Testing a verbal rote learning paradigm in overnight-deprived smokers, Andersson and Post¹⁰⁰ reported that after the first cigarette, anticipatory responding was improved in the placebo compared to the nicotine condition, but after the second cigarette, there was no difference between conditions. Another study reported that, after learning a word-pair list, smoking a cigarette reduced errors when subjects were tested 1 week later.¹⁰¹

The effects of nicotine and smoking on memory have been widely investigated. In two studies conducted with 10-h abstinent smokers,^{102,103} most subjects recalled a greater number of words after nicotine tablets or cigarettes; however, some subjects' recall improved after placebo tablets or denicotinized cigarettes, and some showed no difference between conditions. More recent studies with 12- to 24-h abstinent smokers found that nicotine nasal spray⁸¹ and SC nicotine injections⁷⁹ improved recognition memory. In a study with minimally tobacco deprived (1 h) smokers, three experiments found no effect of smoking after word list presentation on delayed intentional word recall.¹⁰⁴ In contrast, three experiments found improved free recall when subjects either smoked^{104,105} or received 2-mg polacrilex gum¹⁰⁶ before list presentation. Krebs et al.¹⁰⁷ reported that subjects' recall of prose passages was better after smoking a 0.7-mg nicotine cigarette compared to 0.1- or 1.5-mg nicotine cigarettes, suggesting that optimal arousal was produced by the medium, compared with the high, nicotine-containing cigarette. Reaction time on the Sternberg memory test, which measures scanning and retrieval from short-term memory, was faster after smoking^{75,108} and administration of nicotine polacrilex¹⁰⁹ compared to placebo conditions; however, Foulds et al.⁷⁹ reported no effect of SC nicotine on the Sternberg memory test in 24-h abstinent smokers and nonsmokers.

In contrast to these positive effects of nicotine on memory, three studies^{86,93,110} reported no effect of nicotine on tests of immediate and delayed recall in nicotine-deprived smokers, and Houston et al.¹¹¹ reported that immediate and delayed recall was impaired after smoking a nicotine cigarette compared to a nicotine-free cigarette. In studies of nondeprived smokers or nonsmokers, two reported that nicotine improved some aspects of memory in patients with Alzheimer's disease,^{77,112} two found enhanced reaction time on the Sternberg memory test,^{78,109} four reported no effect of nicotine on tests of immediate and delayed recall,^{76,77,91,113} and two found that nicotine polacrilex impaired immediate and/or delayed recall accuracy.^{83,114} Foulds et al.⁷⁹ reported that SC nicotine enhanced response time but decreased accuracy in a digit recall test in nonsmokers.

Several studies have examined the effect of nicotine on other cognitive abilities. Snyder and Henningfield⁸⁶ reported that polacrilex (2 and 4 mg) enhanced response time but had no effect on accuracy in an arithmetic test and had no effect on either speed or accuracy in a test of logical

reasoning in 12-h abstinent smokers. However, Foulds et al.⁷⁹ reported that nicotine injections (0.3 and 0.6 mg, SC) improved response time on the logical reasoning test in 24-h deprived smokers. Five studies conducted with nonsmokers reported no effect of nicotine on several cognitive tests, including the ability to generate correct answers to word and number problems¹¹⁴ and logical reasoning and mental arithmetic.^{79,83,91,113}

4.1.3.5 Summary

As discussed previously, results of studies conducted with nicotine-deprived smokers are difficult to interpret. Without pre-deprivation baseline data, which few studies report, it is difficult to conclude whether nicotine reversed deprivation-induced deficits or enhanced performance beyond that observed in the nondeprived state. In general, however, nicotine and smoking at least reversed deprivation-induced deficits in certain abilities in abstinent smokers, but such beneficial effects have not been observed consistently across a range of performance measures. For example, about half of the studies that measured sustained attention and memory reported a positive effect of nicotine; however, the effects were limited to some subjects or one aspect of test performance.

The strongest conclusions concerning the effects of nicotine and smoking on human performance can be drawn from studies conducted with nondeprived smokers and nonsmokers. These studies indicated that nicotine enhanced finger tapping rate and motor responding in tests of focused and divided attention. Additionally, nicotine produced faster motor responses in the Sternberg memory test, enhanced recognition memory, and reversed the vigilance decrement in a sustained attention test. However, no studies reported true enhancement of sensory abilities, selective attention, learning, and other cognitive abilities.

4.1.4 Sedative-Hypnotics: Benzodiazepines

Since their advent in the 1960s, benzodiazepines have been prescribed widely as anxiolytic and sedative-hypnotic medications, essentially replacing barbiturates because of their greater safety margin. Compared with barbiturates, an acute benzodiazepine overdose is much less likely to produce fatal respiratory depression.²⁰ There are currently more than a dozen benzodiazepines available for medical use; all produce sedation with varying potency. Benzodiazepines with longer duration of action, such as diazepam and lorazepam, are typically prescribed for the treatment of anxiety disorders, whereas those with shorter duration of action, such as triazolam, are used as hypnotics for insomnia. A concern with benzodiazepines being used at night to induce sleep has been the potential for sedation and impaired performance the next day. A review of 52 studies¹¹⁵ indicated that all benzodiazepine hypnotics, at high enough doses, produced next-day performance impairment. The degree of impairment was dose related, suggesting that the lowest effective hypnotic dose should be prescribed.

As with all drugs that produce changes in mood, benzodiazepines have the potential to be abused,^{116,117} and methodologies have been developed to test the abuse liability of benzodiazepines and related drugs in the laboratory.¹¹⁸ The pattern of benzodiazepine abuse varies from occasional episodes of intoxication to daily, compulsive use of large doses. Tolerance and physical dependence develop with continued use, such that individuals taking therapeutic doses of benzodiazepines for several months typically experience withdrawal symptoms even if the dose is gradually tapered.²⁰ The benzodiazepine withdrawal syndrome includes insomnia, restlessness, dizziness, nausea, headache, inability to concentrate, and fatigue. Although unpleasant, benzodiazepine withdrawal is not life-threatening, unlike withdrawal from barbiturates.

The effects of benzodiazepines have been studied extensively with respect to human performance and cognition. Because of their sedative effects, not surprisingly, benzodiazepines generally impair all aspects of performance.^{7,119} However, some decrements, such as the well-studied anterograde amnesia, have been shown to be independent of general sedation.¹² Benzodiazepines will

be considered as the prototypic sedative-hypnotic drug, recognizing that other CNS depressant drugs, such as barbiturates and ethanol, produce somewhat distinct performance impairment profiles. In the studies reviewed, benzodiazepines were administered PO.

4.1.4.1 Sensory Abilities

Consistent with their depressant and sedative effects, benzodiazepines administered acutely typically decrease CFF threshold.^{119,120} Specifically, significant decreases have been reported for 1 mg alprazolam, 10 mg diazepam, and 15 mg quazepam;¹²¹ 4 to 11 mg midazolam;¹²² 7.5 to 50 mg oxazepam;¹²³ 1 and 2 mg lorazepam;¹²⁴ and 0.5 mg triazolam and 1 mg flunitrazepam.¹²⁰ As is evident, this effect on CFF threshold was observed at therapeutic doses of each drug, and when multiple doses were tested, the effect was dose-related. However, there are reports of acute, therapeutic doses of diazepam (5 mg)¹²⁵ and lorazepam (1 and 2 mg)^{125,126} having no effect on CFF threshold. One study investigating numerous benzodiazepines¹²⁰ reported next-day impairment after acute doses of triazolam (0.5 mg) and lormetazepam (1 to 2 mg). No studies were found that examined the effect of chronic benzodiazepine administration on CFF threshold.

Blom et al.¹²¹ recorded horizontal saccadic eye movements as subjects viewed the successive illumination of red light stimuli. They reported that alprazolam, diazepam, and quazepam reduced peak saccadic velocity; alprazolam produced the greatest degree of impairment. Maximal reductions occurred 1 to 4 h after dosing, and effects had not returned to placebo levels at 8 h. Rettig et al.¹²⁷ reported that 1 mg lormetazepam and 15 mg midazolam given the night before increased imbalance of the ocular muscles as measured by the Maddox Wing test. This muscular imbalance produces strabismus, which is the inability of both eyes to converge directly on a visual stimulus. Such ocular impairment could be the basis of a wide range of benzodiazepine-induced performance deficits.

4.1.4.2 Motor Abilities

Numerous studies have reported that various benzodiazepines decrease finger tapping rate.^{119,122,124,128} Kunsman et al.¹¹⁹ noted that finger tapping rate was generally less sensitive to the effects of benzodiazepines than more complex tasks, such as reaction time and tracking. However, the studies reporting decreases in tapping rate used doses that were in the therapeutic range; thus simple motor skills can be impaired at clinically relevant doses.

A large number of studies have shown that benzodiazepines impair gross motor coordination, as measured by the ability to balance on one leg and the circular lights test. Alprazolam (0.5 to 2 mg),¹²⁹ lorazepam (1 and 4 mg),^{130,131} and triazolam (0.25 to 0.75)^{132–135} impaired balance or circular lights performance in a dose-related manner. In a population of sedative abusers, acute administration of 40 or 80 mg diazepam and 1 or 2 mg triazolam impaired circular lights performance, and diazepam, but not triazolam, impaired performance the next day.¹³⁶ Stoops and Rush¹³⁷ reported that tolerance to impaired performance on the circular lights task developed over several sessions of triazolam (0.375 mg) administration. Bond et al.¹²⁸ reported that 1 mg alprazolam increased body sway as measured in an automated ataxiometer.

In contrast to these reports of benzodiazepine-induced motor impairment, Kumar et al.¹³⁸ found that chronic administration of 1 mg lorazepam and 0.5 mg alprazolam for 5 days had no effect on fine motor coordination as assessed using a standard pegboard test. Additionally, Tobler et al.¹³⁹ reported that performance on a typing test was not impaired the day after an acute dose of 7.5 mg midazolam.

4.1.4.3 Attentional Abilities

The effects of benzodiazepines on reaction time tests and the DSST have been investigated in many studies, the majority of which reported impairment of attentional abilities necessary to

perform such tests successfully. Because these tests typically are of short duration (less than 5 min), focused attention is primarily required, although other abilities are also involved. Numerous studies have reported that simple or choice reaction time to visual stimuli was increased (slowed) by acute, therapeutic doses of various benzodiazepines, including adinazolam,¹⁴⁰ alprazolam,¹²⁹ diazepam and flunitrazepam,¹⁴¹ lorazepam,^{130,142} oxazepam,¹²³ temazepam,¹¹⁹ and triazolam.¹³² Linnola et al.^{143,144} reported that diazepam, alprazolam, and adinazolam impaired reaction time and accuracy in a word recognition test. Flurazepam (30 mg, but not 15 mg) produced next-day impairment of simple and choice visual reaction time, whereas 15 mg midazolam had no residual effect.¹⁴⁵ In contrast, diazepam (5 mg) and lorazepam (1 mg) had no effect on an auditory reaction time test.¹²⁵ It is possible that, compared with visual tests, auditory reaction time tests are less sensitive to the impairing effects of benzodiazepines. To investigate this, Pompeia et al.¹⁴⁶ compared the effects of equipotent doses of lorazepam and flunitrazepam on visual and auditory event-related potentials. Both benzodiazepines produced performance decrements on auditory delayed recall; however, flunitrazepam increased P3 latencies in both visual and auditory modalities whereas lorazepam increased visual latencies only.

Like reaction time tests, nearly all studies have reported that acute administration of benzodiazepines impair performance on the DSST. Lorazepam (1 to 9 mg),^{125,130,142,147–149} triazolam (0.25 to 0.75 mg),^{132,134,135,148,150–153} alprazolam (0.5 to 4 mg),^{129,147} temazepam (15 to 60 mg),^{119,150} diazepam (5 to 10 mg),^{147,154} clonazepam,¹⁵⁵ and estazolam (1 to 4 mg)¹⁵² have been shown to impair response speed and/or accuracy on the DSST in a dose-related manner. However, Kelly et al.¹⁵⁶ reported that diazepam (5 or 10 mg) had no effect on DSST performance. It is unlikely that low doses of diazepam accounted for the lack of effect, as suggested by Kelly et al.,¹⁵⁶ because numerous studies have reported DSST impairment after 10 mg diazepam.⁷ In a test similar to the DSST, symbol copying, Saano et al.¹²⁵ reported no effect of diazepam (5 mg) and lorazepam (1 mg). Acute triazolam (0.375 mg) administration decreased the number of trials completed on the DSST task, but tolerance to this decrement developed with each of three subsequent doses.¹³⁷

Another test requiring focused attention is digit or letter cancellation, in which subjects mark through a certain numeral in a page of random numbers or a certain letter in a page of text or random letters. The typical duration of cancellation tests is 1 to 2 min. Two studies reported that diazepam (10 or 15 mg)¹⁵⁷ and lorazepam (1 and 2 mg)¹²⁴ impaired digit cancellation performance. Interestingly, Brown et al.¹⁵⁷ found that impaired focused attention was not correlated with the ability to encode associative information. These studies confirm numerous previous studies that reported benzodiazepine-induced decrements in cancellation tests.⁷

Brief tests of tracking abilities can also be considered tests of focused attention. In such tests, subjects attempt to maintain a moving target within a certain area of the video monitor or a cursor within a moving target. Tracking performance is uniformly impaired by benzodiazepines at doses similar to those reported above for reaction time and DSST impairment.^{119,143,144} One study investigating the effects of multiple doses of three benzodiazepines reported that lorazepam produced the greatest degree of tracking impairment, followed by alprazolam and then diazepam.¹⁴⁷ Because the manipulandum used to control the moving target in some studies was a steering wheel, tracking tests have occasionally been considered laboratory tests of driving ability. In studies of on-road driving, Volkerts et al.¹⁵⁸ reported that driving was impaired the morning after dosing with oxazepam (50 mg) and slightly impaired after lormetazepam (1 mg). Brookhuis et al.¹⁵⁹ found that next-day driving was significantly impaired after flurazepam (30 mg) and less impaired after lormetazepam (2 mg). Diazepam (15 mg) impaired performance on a clinical test for drunkenness, which comprised 13 tests assessing motor, vestibular, mental, and behavioral functioning.¹⁶⁰

Compared with focused attention, fewer studies have examined the effects of benzodiazepines on selective attention. Two studies have shown that performance on the Stroop test was impaired by lorazepam.^{119,131} Acute administration of triazolam and lorazepam produced dose-dependent decrements in response rate and accuracy in a simultaneous matching-to-sample task, which required subjects to determine which of two comparison visual stimuli was identical to the sample stimu-

lus.^{148,161} The drug effects differed as a function of task difficulty, such that the benzodiazepine-induced impairment was reduced when discriminability of the non-matching stimulus was increased.

Benzodiazepines have been shown to impair divided attention.¹¹⁹ Two groups of investigators reported that oxazepam (7.5 to 50 mg)¹²³ and alprazolam (0.5 mg)¹⁶² impaired performance on a test that required subjects to divide their attention between a central tracking task and responding to stimuli in the peripheral visual field. Using a similar test of divided attention, Moskowitz et al.¹⁴⁵ found that 30 mg flurazepam and 15 mg midazolam impaired performance the day after drug administration.

Consistent with the other types of attention, benzodiazepines impair performance in tests of sustained attention or vigilance.^{14,143,145} There is no evidence that benzodiazepines exacerbate the vigilance decrement normally observed during prolonged, tedious tests. The impairment caused by benzodiazepines in tests of sustained attention is not secondary to sedation, but rather a direct effect on perceptual sensitivity, resulting in decreased hits and increased response time in detecting stimulus targets.

4.1.4.4 Cognitive Abilities

The most widely studied aspect of cognition with respect to benzodiazepines is memory.^{12,163} One of the most reliable effects of benzodiazepines is to impair recall of information presented after drug administration (anterograde amnesia). In contrast, information presented before administration of benzodiazepines is not affected. The memory decrement produced by benzodiazepines is a function of task difficulty, such that little or no impairment is observed for immediate recall of a few items, whereas more complex or delayed memory tests reveal profound impairment.¹² The benzodiazepine antagonist flumazenil has been used to block the sedative effects of benzodiazepines, but the amnesic effect was not affected, suggesting that benzodiazepine-induced amnesia is independent of sedation.^{122,164} It has also been demonstrated that some benzodiazepines selectively impaired explicit memory (e.g., recall of a word list), but left other aspects of memory intact.¹⁶³ In this way, benzodiazepines have been used as pharmacological tools to identify distinct memory processes.

Roy-Byrne et al.¹⁶⁵ reported that diazepam (10 mg) impaired attentional processes during auditory presentation of a word list and immediate recognition of words that had been presented twice; however, naming examples of a category, such as vegetables (semantic memory), and self-evaluation of memory performance (meta-cognition) were not affected. Triazolam (0.25 to 0.5 mg) impaired free recall of a word list, but had no effect on implicit (memory without awareness of the source of information) or semantic memory.^{166,167} Linnoila et al.¹⁴³ reported that adinazolam (15 or 30 mg) impaired attention during list presentation, but had no effect on delayed (1 min) free recall of words. Using a battery of tests that assessed numerous memory functions, Bishop et al.¹²⁴ reported that lorazepam (1 and 2 mg) impaired explicit (free recall), semantic, and implicit memory, but had no effect on working memory (manipulation of information for less than 30 s) and procedural memory (knowledge required for skills reflected as improved performance with practice). Similarly, a higher dose of lorazepam (2.5 mg) disrupted several memory processes (delayed recall, implicit and semantic memory), but did not affect short-term memory.¹⁶⁸ Such selective drug effects on memory and similarly selective clinical amnesic syndromes resulting from brain injury or disease¹⁶³ have allowed a greater understanding of cognitive functioning and the processes subserving learning and memory.

A large number of studies have investigated the effect of acute benzodiazepine administration on either immediate or delayed recall or recognition of word lists, numbers, or pictures in healthy volunteers. Impaired memory has been reported for adinazolam (20 to 30 mg),¹⁴⁰ alprazolam (0.5 to 2 mg),^{129,144,169} diazepam (5 to 15 mg),^{157,170} estazolam (1 to 4 mg),¹⁵² lorazepam (1 to 4 mg),^{130,171} temazepam (15 to 60 mg),¹⁵⁰ and triazolam (0.25 to 0.75 mg).^{132–135,150,152,172} Acute administration of triazolam¹³⁵ and lorazepam¹³¹ has been observed to significantly impair working memory. In addition, Buchanan et al.¹⁷³ reported that triazolam (0.25 mg) interfered with the facilitating effect

that emotional stimuli have on long-term memory (both delayed recall and recognition). Diazepam (15 mg) also was reported to produce impairments in facial emotional recognition.¹⁷⁴ Testing subjects with histories of sedative abuse, Roache and Griffiths^{136,142} reported that immediate and delayed recall and recognition of digits and symbols were impaired by diazepam (40 or 80 mg), lorazepam (1.5 to 9 mg), and triazolam (1 or 2 mg). After 5 days of dosing healthy subjects with either alprazolam (0.5 mg) or lorazepam (1 mg), anterograde amnesia was observed for word lists.¹³⁸ Hindmarch et al.¹²⁰ examined the effects of several benzodiazepines on the Sternberg memory test, which measures scanning and retrieval from short-term memory. They reported that acute administration of flunitrazepam (1 mg), lormetazepam (1 to 2 mg), and triazolam (0.5 mg) significantly slowed response time on the test and that performance remained impaired the next day with lormetazepam and triazolam. However, Kelly et al.¹⁵⁶ reported no effect of diazepam (5 and 10 mg) on the Sternberg test.

The effect of a number of benzodiazepines has been investigated on the repeated acquisition and performance of response sequences task, which comprises separate acquisition (learning) and performance components.¹⁷⁵ This task thus allows independent assessment of drug effects on acquisition of new information and performance of already learned information. In general, doses of benzodiazepines that increased errors in the acquisition component did not impair the performance component, although high doses decreased response rate and increased errors in both components. Impairment of acquisition of the response sequence has been reported following acute administration of alprazolam (1 to 3 mg),¹⁷⁵ diazepam (5 to 30 mg),^{11,175,176} estazolam (1 to 4 mg),¹⁵² lorazepam (2.8 to 5.6 mg),¹⁴⁹ temazepam (15 to 60 mg),¹⁵⁰ and triazolam (0.375 to 0.75 mg).^{150–152,175,176} In these studies, only the highest doses impaired the performance component of the task. In one of the few studies to examine the chronic effects of benzodiazepines on cognitive processes, Bickel et al.¹⁷⁷ administered diazepam (80 mg daily) for 3 days to sedative abusers and found increased errors and decreased response rate in the acquisition component on day 1 that decreased on days 2 and 3, suggesting the development of tolerance. In the performance component, response rate was decreased on day 1; the magnitude of effect decreased over days. Performance error rate was relatively unaffected.

Few studies have examined the effects of benzodiazepines on other cognitive abilities. Rusted et al.¹⁷⁰ reported that 5 and 10 mg diazepam impaired performance on a logical reasoning test, but had no effect on a mental rotation task. Judd et al.¹⁷⁸ found that 30 mg flurazepam, but not 15 mg midazolam, impaired arithmetic (addition) abilities the day after drug administration. In contrast, flurazepam had no effect on reading comprehension.

4.1.4.5 Summary

When administered acutely to nontolerant, healthy volunteers, therapeutic doses of benzodiazepines produce sedation, which typically impairs most aspects of performance in a dose-dependent manner. In patients taking benzodiazepines medically and in individuals who abuse benzodiazepines recreationally, both of whom have developed tolerance, it is necessary to increase the dose of benzodiazepine to observe impaired performance. Benzodiazepines have been shown to decrease CFF threshold, a direct indication of CNS depression, and to impair ocular performance. Motor abilities are impaired by benzodiazepines, including fine (finger tapping) and gross (balance, circular lights, and body sway) motor coordination. Numerous studies have documented that benzodiazepines impair tests requiring focused, selective, divided, and sustained attention. One of the best-studied cognitive effects of benzodiazepines is their ability to produce anterograde amnesia, memory loss for information presented after drug administration. It has been demonstrated that these memory deficits are not secondary to benzodiazepine-induced sedation and that explicit memory (free recall of presented stimuli) functions are typically impaired, whereas other memory processes can remain unaffected. Benzodiazepines have also been shown to impair the acquisition (learning) of new information.

4.1.5 Opioid Analgesics and Anesthetics

The class of drugs referred to as opioids consists of a wide range of naturally occurring derivatives from the opium poppy, *Papaver somniferum*, such as morphine and codeine; semisynthetic derivatives from opium, such as heroin and hydromorphone; and completely synthetic opioids, such as meperidine and fentanyl. The primary pharmacological effect of all opioids is analgesia; a common side effect is sedation. At high doses, respiratory depression occurs, which is the usual cause of death from acute opioid overdose. The full range of clinical pain can be effectively treated with various opioids, and fentanyl and related synthetic congeners (sufentanil, alfentanil) are generally used clinically as anesthetics, but are also used for postoperative analgesia.

Opioids can be classified according to their pharmacological actions into those that function like morphine, producing their agonist effects primarily through the mu opioid receptor, and those that produce mixed effects, such as agonist-antagonists or partial agonists.¹⁷⁹ Mixed agonist-antagonists function as agonists at one type of opioid receptor (e.g., delta or kappa) and as an antagonist at other (e.g., mu) receptors. Partial agonists produce only limited effects at a given receptor. Morphine-like opioids are used clinically for moderate to severe pain, whereas agonist-antagonists and partial agonists produce less analgesia and are thus useful in the treatment of mild pain.

Previous reviews have concluded that opioids produce minimal impairment of human performance even at high doses.^{179,180} However, more recent reviews^{16,181} challenge this benign notion. In healthy, nontolerant research subjects, opioids impair psychomotor performance to a greater extent than cognitive abilities. Typically, opioids slow responses in tests requiring speed, but do not impair test accuracy. In contrast, individuals who have developed tolerance to opioids, such as patients suffering chronic pain¹⁸¹ or persons maintained on methadone,¹⁸⁰ generally show little or no behavioral impairment after administration of their maintenance dose. The time required for tolerance to develop to any performance-impairing effects of methadone has been estimated at 3 to 4 weeks in methadone-maintained patients.¹⁸⁰ The studies reviewed here report the performance effects of opioids in nontolerant research volunteers, unless otherwise indicated.

4.1.5.1 Sensory Abilities

Studies investigating the effects of morphine, meperidine, buprenorphine, and nalbuphine on CFF threshold have, in general, found impaired functioning, consistent with the CNS depressant effect of opioids.¹⁶ Veselis et al.¹⁸² targeted fentanyl plasma concentrations of 1.0, 1.5, and 2.5 ng/ml using continuous IV infusion and found that CFF threshold was decreased at 1.5 ng/ml, whereas other performance measures were affected only at concentrations greater than 2.5 ng/ml. Morphine (10 mg, PO) was also found to decrease CFF threshold.¹⁸³ In contrast, pentazocine (30 mg) had no effect on CFF threshold;¹⁸⁴ however, other studies using higher doses of pentazocine have reported decreased CFF threshold.¹⁶

Zacny and colleagues have examined the effects of several opioids on the Maddox Wing test, a measure of ocular muscle imbalance indicating divergence of the eyes. Administration of morphine (2.5 to 10 mg, IV),¹⁸⁵ butorphanol (0.5 to 2.0 mg, IV),¹⁸⁶ dezocine (2.5 to 10 mg, IV),¹⁸⁷ pentazocine (30 mg, IM),¹⁸⁴ hydromorphone (1.3 mg, IV),¹⁸⁸ nalbuphine (2.5 to 10 mg, IV),¹⁸⁹ and an anesthetic combination of propofol and alfentanil¹⁹⁰ impaired performance on the Maddox Wing test in a dose-related manner. In contrast, fentanyl (25 to 100 µg, IV)¹⁹¹ and meperidine (0.25 to 1.0 mg, IV)¹⁹² were found to have no effect on Maddox Wing performance. Additionally, fentanyl (50 µg, IV)¹⁹³ and an IV combination of fentanyl (50 µg) plus propofol (35 mg),¹⁹⁴ an IV anesthetic, had no effect on the Maddox Wing test. Thus, many opioids have been shown to decrease CFF threshold, a measure of overall CNS arousal, whereas some, but not all, opioids impaired ocular muscle balance.

4.1.5.2 Motor Abilities

Compared with other measures of performance, few studies have investigated the effects of opioids on pure motor abilities, such as finger tapping and coordination.¹⁶ Kerr et al.¹⁹⁵ used individually tailored steady-state infusions to target several plasma concentrations of morphine (20, 40, and 80 ng/ml). They found that only the high dose of morphine impaired finger tapping and the ability to maintain low constant levels of isometric force, which required precise motor control. Finger tapping rate was decreased in a group of patients with cancer who had received an increase of greater than 30% in their dose of opioid (morphine, hydromorphone, oxycodone, or codeine) compared to a group of patients who did not receive a dosage increase.¹⁹⁶ Finger tapping rate was also decreased following a short-term anesthetic regimen of propofol and alfentanil.¹⁹⁰ In contrast, pentazocine (30 mg) had no effect on finger tapping.¹⁸⁴ Butorphanol (0.5 to 2 mg, IV) and nalbuphine (2.5 to 10 mg, IV) were shown to impair a measure of eye–hand coordination.¹⁸⁹ Slightly over half the studies investigating the effect of opioids on body sway, a measure of gross motor coordination, reported impairment.¹⁶

4.1.5.3 Attentional Abilities

A relatively large number of studies have investigated the effects of opioids on tests requiring focused attention. Morphine (2.5 to 10 mg, IV)¹⁸⁵ and propofol (70 mg, IV)¹⁹³ impaired an auditory simple reaction time test, and fentanyl (1 to 2.5 ng/ml, IV)¹⁸² impaired a visual choice reaction time test. Jenkins et al.¹⁹⁷ reported that IV (3 to 20 mg) and smoked (2.6 to 10.5 mg) heroin impaired performance on a simple visual reaction time task. However, other studies reported no effect of butorphanol (0.5 to 2.0 mg, IV),¹⁸⁶ fentanyl (25 to 100 µg, IV),¹⁹¹ meperidine (0.25 to 1.0 mg, IV),¹⁹² and nalbuphine (2.5 to 10 mg, IV)¹⁸⁹ on an auditory simple reaction time test. It may be that visual reaction time tests are more sensitive than auditory tests to the effects of opioids, which would be consistent with opioid-induced impairment on the Maddox Wing test, discussed in the preceding section.

Numerous studies have reported that performance on the DSST was impaired by various opioids, including morphine (2.5 to 10 mg),^{185,198} fentanyl (1 to 2.5 ng/ml),¹⁸² pentazocine (30 mg),¹⁸⁴ butorphanol (0.5 to 2 mg),¹⁸⁶ dezocine (2.5 to 10 mg),¹⁸⁷ propofol (22 to 70 mg),^{193,199} nalbuphine (2.5 to 10 mg, IV),¹⁸⁹ and the combination of fentanyl (50 µg) plus propofol (35 mg).¹⁹⁴ In contrast, meperidine was found to have no effect on the DSST.¹⁹² Because the DSST is a timed test, it would appear that opioids slow speeded responses in a fairly consistent manner in opioid-naïve subjects. However, in opioid abusers or opioid-dependent persons, Preston and colleagues have reported no effect on DSST performance of several opioids, including morphine (7.5 to 30 mg, IM),²⁰⁰ hydromorphone (0.125 to 3 mg, IM),²⁰¹ buprenorphine (0.5 to 8 mg, IM),²⁰² pentazocine (7.5 to 120 mg, IM),²⁰³ butorphanol (0.375 to 1.5 mg, IV),²⁰⁴ and nalbuphine (3 to 24 mg, IM).²⁰⁵

Many of these same studies have also reported opioid-induced impairment of a 1-min tracking test in which subjects tracked a randomly moving target on a video monitor with a mouse-controlled cursor. This task measures visual-motor coordination and focused attentional abilities and was impaired by fentanyl (25 to 100 µg, IV),^{191,193} meperidine (0.25 to 1.0 mg, IV),¹⁹² butorphanol (0.5 to 2 mg, IV),¹⁸⁶ dezocine (2.5 to 10 mg, IV),¹⁸⁷ and propofol (0.08 to 0.32 mg/kg, IV) alone¹⁹⁹ and in combination with fentanyl (50 µg, IV).¹⁹⁴ Morphine (2.5 to 10 mg, IV) had no effect on the same tracking task.¹⁸⁵ In one of the few studies to investigate the effects of opioids on divided attention, pentazocine (30 mg, IM) was shown to impair the choice reaction time component, but had no effect on the tracking component of a divided attention test.¹⁸⁴ Fentanyl (100 µg, IV) slowed reaction time and movement time in a driving simulator.²⁰⁶ However, patients suffering noncancer pain receiving transdermal fentanyl for at least 2 weeks showed no impairment on a battery of computerized tests designed to assess driving ability.²⁰⁷ Further, Galski et al.²⁰⁸ showed that patients on chronic opioid treatment were not impaired in off-road tests and in a driving simulator. Some

studies with morphine have documented impaired sustained attention; however, the few studies that have been conducted with other opioids found no effect on a variety of vigilance tasks.^{16,183}

4.1.5.4 Cognitive Abilities

A relatively large number of studies have examined the effects of opioids on memory and other cognitive functions; a minority of these studies have reported impairment.¹⁶ Kerr et al.¹⁹⁵ found that steady-state levels of morphine (20 to 80 ng/ml, IV) slowed reading time of prose passages. When asked questions about the passage immediately after reading, subjects' recall was not impaired, but delayed questioning revealed impaired comprehension. In methadone-maintained patients, a single methadone dose equal to 100% of their daily stabilization dose impaired delayed recall of a prose passage, whereas 50% of their daily dose slightly improved recall.²⁰⁹ Fentanyl (1 to 2.5 ng/ml, IV) was shown to impair a range of memorial abilities, including auditory-verbal recall of common words, picture recall, and digit recall.¹⁸² In a group of patients with cancer whose opioid (morphine, hydromorphone, oxycodone, or codeine) dose was increased by at least 30%, decreases were observed in an arithmetic test, backward digit span, and a test of visual memory.¹⁹⁶ Propofol (0.08 to 0.32 mg/kg, IV) impaired delayed, but not immediate, recall of a word list only at the highest dose level.¹⁹⁹ In another study, propofol (70 mg, IV), but not fentanyl (50 µg, IV) impaired immediate free recall of words.¹⁹³ Walker et al.¹⁸⁹ reported that butorphanol (0.5 to 2 mg, IV), but neither nalbuphine nor pentazocine, slowed responding on a test of logical reasoning.

4.1.5.5 Summary

Administration of acute, therapeutic doses of opioids to nontolerant research subjects produces effects typical of CNS depressant drugs, including decreased CFF threshold. Many, but not all, opioids produce ocular muscle imbalance as assessed in the Maddox Wing test. Finger tapping and gross motor coordination were found to be impaired in some, but not all, studies. A relatively large number of studies have reported that opioids produce decrements in brief tests requiring focused attention and fine motor coordination, such as visual reaction time, DSST, and visual-motor tracking. Very few studies have examined the effects of opioids on selective, divided, and sustained attention. The effects of opioids on cognitive functioning are mixed, with the majority of studies indicating no impairment, but some well-designed studies showing decrements in memory. When administered to opioid-tolerant individuals, such as opioid abusers or patients with chronic pain, opioids typically produce little or no performance impairment, including impairment of skills related to driving.

4.1.6 Marijuana

Marijuana consists of the dried and crushed leaves and stems of the plant *Cannabis sativa*, which grows worldwide. In the U.S., marijuana is typically rolled in cigarettes (joints) or cigar wrappers (blunts) and smoked. In various parts of the world, other preparations of the cannabis plant are eaten or fumes from the ignited plant material are inhaled. The acute effects of smoked marijuana and Δ^9 -tetrahydrocannabinol (THC), the primary psychoactive constituent of marijuana, have been investigated in numerous studies over the past several decades.^{10,11} One of the most reliable behavioral effects of acute marijuana is impairment of memory processes; less consistent impairment has been reported for motor and attentional tests. Documenting the effects of chronic marijuana use has been somewhat elusive, with early studies reporting no impairment of cognitive functioning;²¹⁰ however, more recent studies have shown chronic marijuana users to be impaired in perceptual-motor abilities,²¹¹ attention,^{212,213} mathematical and verbal skills,²¹⁴ and learning and memory.^{213,215}

Unless otherwise noted, the studies reviewed here examined the acute effects of marijuana and were conducted with experienced marijuana users who smoked standard marijuana cigarettes provided by the National Institute on Drug Abuse (NIDA). These marijuana cigarettes resemble in

size an unfiltered tobacco cigarette, weigh 700 to 900 mg, and are assayed by NIDA to determine the percentage of THC by weight. Doses are typically manipulated by using cigarettes that differ in THC content or by varying the number of puffs administered to subjects (five to eight puffs are equivalent to one cigarette). Placebo cigarettes have had active THC removed chemically from the plant material, but when burned, smell identical to an active marijuana cigarette.

Over the years, an intriguing research question with important practical implications has been whether marijuana impairs performance beyond the period of acute intoxication, which typically lasts 2 to 6 h after smoking one or two cigarettes. Studies have documented performance decrements 12 to 24 h after smoking marijuana.²¹⁶ One series of studies reported that 24 h after smoking a single marijuana cigarette (2.2% THC), experienced aircraft pilots were impaired attempting to land a plane in a flight simulator;^{217,218} however, a third study failed to replicate this next-day effect.²¹⁹ In another series of studies, a comprehensive battery of tests revealed that only time estimation²²⁰ and memory²²¹ were impaired 9 to 17 h after smoking two marijuana cigarettes (2.1 to 2.9% THC), leading the authors to conclude that evidence for next-day performance effects of marijuana was weak. Yet another series of studies found next-day impairment on tests of memory and mental arithmetic after smoking two or four marijuana cigarettes (2.6% THC) over a 4-h period,²²² but not after smoking one marijuana cigarette.^{222,223} Thus, residual impairment after acute marijuana dosing appears to be a dose-related phenomenon, with effects more likely to be observed at higher marijuana doses.

Recently, two studies have examined the residual effects of long-term marijuana use.^{224,225} In both studies, marijuana smokers were abstinent for 28 days during which time a battery of neuropsychological tests was repeatedly administered. Daily, chronic smokers were compared to less frequent smokers. Bolla et al.²²⁴ reported that daily smokers were impaired on tests of memory, executive functioning, and psychomotor skills after 28 days of marijuana abstinence. In contrast, Pope et al.²²⁵ found neuropsychological impairment during the first week of abstinence, but by day 28, there were no differences between daily smokers and control subjects. Both studies found that daily smokers evidenced greater impairment than less frequent smokers, which is consistent with the dose-related effect noted above for acute marijuana studies.

Another controversial issue has been the amotivational syndrome supposedly caused by heavy, chronic marijuana use. This syndrome has been characterized by feelings of lethargy and apathy and an absence of goal-directed behavior.^{226,227} However, studies conducted in countries where segments of the population use marijuana heavily^{228–230} and laboratory-based studies in the U.S.^{231,232} have not found empirical support for an amotivational syndrome.

4.1.6.1 Sensory Abilities

Few studies have investigated the effects of marijuana on CFF threshold. Block et al.²³³ reported that one marijuana cigarette (2.6% THC) decreased CFF threshold compared to placebo. However, Liguori et al.²³⁴ found no effect of marijuana (1.8 and 4.0% THC) on CFF threshold. Although more a perceptual process than a sensory ability, a commonly reported effect of marijuana is to increase the subjective passage of time relative to clock time. This typically results in subjects either overestimating an experimenter-generated time interval²²⁰ or underproducing a subject-generated interval.²³⁵ However, Heishman et al.²³⁶ reported that marijuana (3.6% THC; 4, 8, or 16 puffs) had no effect on either time estimation or production.

4.1.6.2 Motor Abilities

In their review, Chait and Pierri¹¹ indicated that marijuana produced moderate impairment of balance (increased body sway) and hand steadiness. Consistent with this motor impairment, one marijuana cigarette decreased postural balance as subjects attempted to maintain balance while standing on a platform that moved at random intervals,²³⁷ impaired equilibrium in a computerized

test of body sway,²³⁴ and impaired balance in subjects attempting to stand on one leg.²³⁸ Cone et al.²³⁹ found that two marijuana cigarettes (2.8% THC) impaired performance on the circular lights task; however, Heishman et al.²⁴⁰ reported no effect of marijuana (1.3 and 2.7% THC, two cigarettes) on circular lights performance. Marijuana impaired performance in a test of perceptual motor speed and accuracy.²⁴¹ In contrast, several studies have shown that marijuana did not influence finger tapping rate.¹¹

4.1.6.3 Attentional Abilities

A relatively large number of studies have investigated the effects of marijuana on focused attention, including reaction time tests and the DSST. Marijuana (1.8 and 3.6% THC) was shown to slow responding on a simple, visual reaction time task;²⁴² however, others have not found marijuana to impair simple reaction time performance.^{11,40,236} Similarly, some studies have shown that marijuana impairs complex or choice reaction time tasks,^{11,233} whereas others have shown no effect.²³⁴ O'Leary et al.²⁴³ found no effect of a 20-mg marijuana cigarette on reaction time in a dichotic listening task.

In general, marijuana also impaired performance on the DSST. In concentrations ranging from 1.8 to 3.6% THC, marijuana has been shown to decrease number of attempted responses (speed) and/or decrease number of correct responses (accuracy) on the DSST.^{235,236,238,240,242,244–246} Oral THC (10 and 20 mg) also impaired DSST performance.²⁴⁷ However, other studies have reported no effect of marijuana (1.3 to 3.6% THC) on the DSST.^{40,220,248} The reasons for a lack of effect in these latter studies is unclear given that doses of marijuana were comparable and, in one study,²⁴⁸ task presentation was identical to those studies reporting impairment. Marijuana (1.2% THC) also impaired selective attention as evidenced by slower responding and greater interference scores in the Stroop color naming test.²⁴⁹

Divided attention has generally been shown to be impaired by marijuana. Many divided attention tests consist of a central or primary task and a secondary or peripheral task. Several studies have shown that marijuana impaired detection accuracy and/or stimulus reaction time in one or both test components.^{235,245,250} Hart et al.²⁵¹ reported that oral THC (20 mg, q.i.d.) and smoked marijuana (3.1% THC, q.i.d.) decreased tracking speed in a divided attention task. Kelly et al.²⁵² used a complex, 5-min divided attention test, in which an arithmetic task (addition and subtraction of three-digit numbers) was presented in the center of the video monitor and three other stimulus detection tasks were presented in the corners of the monitor. Performance was impaired in a dose-related manner after smoking one marijuana cigarette (2.0 or 3.5% THC). This finding illustrates that marijuana readily disrupts performance in complex tasks requiring continuous monitoring and the ability to shift attention rapidly between various stimuli.

These same attentional abilities are required when operating a motor vehicle. Not surprisingly, laboratory tests that model various components of driving²⁴¹ and standardized tests used by law enforcement officials to determine whether a person can safely drive^{253,254} have been shown to be impaired by marijuana. Liguori et al.²³⁴ reported that smoked marijuana (1.8 and 4.0% THC) increased braking latency in a driving simulator. Finally, tests of on-road driving found that marijuana moderately increased lateral movement of the vehicle within the driving lane on a highway.^{255,256}

Marijuana also impairs sustained attention. In a 30-min vigilance task, hashish users exhibited more false alarms than non-using control subjects.²⁵⁷ This finding is consistent with the observation that the impairing effects of marijuana on sustained attention are most evident in tests that last 30 to 60 min; tests with durations of 10 min are not adversely affected by marijuana.¹¹

4.1.6.4 Cognitive Abilities

Marijuana has been shown to impair learning in the repeated acquisition and performance of response sequences tasks. Increased errors in the acquisition phase were reported after smoked marijuana (2.0 and 3.5% THC)²⁴⁴ and oral THC (10 and 20 mg).²⁴⁷ However, other studies^{40,52} have

found no effect of smoked marijuana on this test, and one study²⁵¹ reported that oral THC (20 mg, q.i.d.) increased the number of completed trials. Block et al.²³³ reported that one marijuana cigarette (2.6% THC) impaired paired-associative learning.

As stated previously, one of the most reliable effects of marijuana is the impairment of memory processes. Numerous studies have found that smoked marijuana decreased the number of words or digits recalled and/or increased the number of intrusion errors in either immediate or delayed tests of free recall after presentation of information to be remembered.^{220,222,233,236,245,246,249,252} Curran et al.²⁵⁸ reported that oral THC (15 mg) impaired explicit memory and a selective reminding task, but had no effect on implicit and working memory. Using an extensive battery of cognitive tests, Block et al.²³³ reported that marijuana (2.6% THC) slowed response time for producing word associations, slowed reading of prose, and impaired tests of reading comprehension, verbal expression, and mathematics. Heishman et al.²²² also found that simple addition and subtraction skills were impaired by smoking one, two, or four marijuana cigarettes (2.6% THC). Finally, Kelly et al.²⁵² reported that marijuana (2.0 and 3.5% THC) slowed response time in a spatial orientation test requiring subjects to determine whether numbers and letters were displayed normally or as a mirror image when they were rotated between 90° and 270°. In contrast to these findings, Hart et al.²⁵⁹ reported that although smoked marijuana (1.8 and 3.9% THC) slowed responding on several measures, it had no effect on accurate performance of tasks measuring cognitive flexibility, arithmetic skills, and reasoning ability.

4.1.6.5 Summary

Laboratory studies in which subjects smoked marijuana have documented that marijuana impaired sensory-perceptual abilities by reducing CFF threshold and by increasing the subjective passage of time relative to clock time. Marijuana impaired gross motor coordination as measured by body sway and postural balance. However, inconsistent findings have been reported for fine motor control; hand steadiness was impaired, whereas several studies have shown no effect of marijuana on finger tapping. Marijuana has been shown to impair complex, but not simple, reaction time tests. A majority of studies have found that marijuana disrupted performance on the DSST. Complex divided attention tests, including driving a vehicle, were readily impaired by marijuana, as were tests requiring sustained attention for more than 30 min. Numerous studies have documented that smoked marijuana and oral THC impaired learning, memory, and other cognitive processes.

4.1.7 Conclusion

It is evident that a large body of literature exists concerning the effects of psychomotor stimulants, nicotine and tobacco, benzodiazepines, opioids, and marijuana on human performance. As a result, we know much in general about the effects of these psychoactive drugs on sensory, motor, attentional, and cognitive abilities. However, there are some gaps in this literature that need to be filled with data from well-designed, well-controlled studies. For example, few studies have investigated the effects of D-amphetamine or cocaine on cognitive abilities, and, for all drugs, sensory and perceptual processes have received little research attention compared with other aspects of behavior. It is also important to continue investigating specific mechanisms underlying general effects of drugs on behavior. For example, we are beginning to understand the differential effects of benzodiazepines on various components of memory;^{124,163} similar studies should be conducted examining the effects of marijuana on memory or the effects of nicotine on cognitive processes. Not only will we learn more about the potentially deleterious effects of drugs on human performance, but drugs can be used as tools to further our understanding of basic processes of performance and cognition.

Two other approaches for future research include the measurement of plasma drug concentrations concomitant with performance and a greater number of drug interaction studies. Very few of the studies reviewed in this chapter provided data on the amount of drug actually delivered to

subjects. This is especially critical in studies with tobacco and marijuana because the large variability in smoking behaviors (e.g., length of puffs and depth of inhalations)^{246,260} and the low bioavailability of smoked drugs^{6,261} result in highly variable delivered drug doses.²⁶² Virtually none of the tobacco studies and only a few of the marijuana studies reviewed reported plasma drug concentrations. Such data are necessary to relate performance impairment with a known drug concentration. Relatively few studies have investigated the interactive effects of drugs on human behavior.^{40,144,151,235} Such basic information is critically needed because the simultaneous use of drugs with different pharmacological effects (e.g., ethanol and marijuana; nicotine and all drugs) is common practice today. It is likely that the combined effect of two or more drugs is very different from that of each drug alone.

Last, laboratory research emphasizing applications of performance effects of psychoactive drugs to the workplace remains relatively uncharted (see Kelly et al., Chapter 4.2 of this volume). Performance assessment batteries need to be tested in the laboratory to determine their validity, reliability, and generalizability to the workplace. Although few performance measures have undergone such rigorous laboratory testing, the methodology exists for assessing the validity, reliability, and sensitivity of a performance task.²⁶³⁻²⁶⁵ Because much of drug-induced impairment observed in the workplace will be subtle in nature, laboratory studies should pay greater attention to long-lasting (next day) drug effects and drug withdrawal effects. Additionally, controlled laboratory studies can provide important information concerning a drug's time course of action and its interaction with other drugs.

4.2 PERFORMANCE-BASED ASSESSMENT OF BEHAVIORAL IMPAIRMENT IN OCCUPATIONAL SETTINGS

**Thomas H. Kelly, Ph.D.,¹ Richard C. Taylor, M.A.,² Stephen J. Heishman, Ph.D.,²
and Jonathan Howland, Ph.D.³**

¹ Department of Behavioral Science, University of Kentucky College of Medicine, Lexington, Kentucky

² Clinical Pharmacology and Therapeutics Branch, National Institute on Drug Abuse, National Institutes of Health, Department of Health and Human Services, Baltimore, Maryland

³ Social and Behavioral Sciences Department, Boston University School of Public Health, Boston, Massachusetts

4.2.1 Introduction

A number of technologies for the assessment of performance impairment have emerged in recent years.¹ These technologies, which include biological sample testing, neuropsychological assessment, personality assessment, and performance testing, are designed to identify risks to safety and/or productivity (e.g., poor health, sleep deprivation, use of behaviorally active drugs/medications), to alter behaviors associated with the development of these risks (e.g., health promotion, reducing drug-taking behavior), and to support the development and evaluation of interventions designed to enhance safety and productivity.² Each of these technologies has strengths and limitations.

Biological sample testing is highly specific for the assessment of risk factors associated with the presence of drugs and/or neurotoxins. The primary advantage of biological sample testing is the reliability and validity with which the presence of these risk factors can be detected (e.g.,

published standards for the development and implementation of drug-testing programs are available).³ If the integrity of testing procedures is maintained, these technologies can provide accurate information regarding prior exposure to a wide variety of agents. There are a number of disadvantages associated with these technologies, however. The costs associated with development and maintenance of testing programs can be substantial. The collection of biological samples can be invasive. The time required to produce a result following collection of a biological sample can be impractical in applications in which immediate results are necessary. Perhaps the most complicated disadvantage associated with biological sample testing technologies available at the current time is that they provide uncertain information regarding performance effects. Drugs (and their metabolites) remain in biological samples for many hours/days after exposure, well beyond the period of time that is associated with performance-impairing effects. The detection of metabolites in biological samples, therefore, does not always provide sufficient information to determine whether or not a drug is producing effects on human performance.

Neuropsychological testing technologies attempt to measure neurological and behavioral function. These technologies generally involve one-time measurements of physiological and behavioral responses to tests, and clinical interpretations of the results of the tests are based, in part, on comparisons with scores (i.e., norms) collected from populations of individuals with similar characteristics (e.g., age, gender, race).⁴ The reliability and validity of neuropsychological testing technologies are regularly and repeatedly tested, and these procedures can be used to assess the acute and long-term effects of environmental perturbations, such as injuries, disease states, and drug exposure, on human capabilities. An appropriately trained professional should conduct neuropsychological test battery administration and interpretation, and as such, the efficiency and expense of this technology may limit its use in applied settings. On the other hand, while designed for acute clinical assessment, many components of neuropsychological test batteries can be administered in a reliable manner on a repeated basis as part of an automated performance testing system. Additional research is needed to determine the validity of the use of components of neuropsychological test batteries in this manner.

Personality testing technologies attempt to identify and measure personality dimensions that differentiate individuals who have increased safety and/or productivity risks (e.g., drug users) from those who do not. Examples of such screening tools include integrity tests, attitude tests, and the measurement of risk factor profiles. Personality testing technologies have been evaluated most critically when used for pre-employment screening; their use in repeated assessments of workers has received less attention. A major concern with regard to this technology is the high rate of false positives (i.e., identification of an individual as being at risk when the individual is, in fact, not at any risk) that has been associated with its use.⁵ Concerns regarding whether these approaches will ever achieve a sufficient level of accuracy to effectively measure performance impairment have been raised.¹

In contrast to neuropsychological testing technologies that are designed for acute clinical assessment, performance testing technologies are designed for repeated measurement of an individual's performance under standardized testing conditions. Clinical evaluations of performance on these tests can be based on population norms (as is the case with many neuropsychological testing technologies) or on deviations from individually determined performance standards established through repeated measurements of an individual's performance (i.e., change from baseline performance). Most performance testing technologies have emerged from laboratory-based research that has occurred over the past three decades (e.g., see Heishman and Myers, Chapter 4.1 of this volume). The development and evaluation of performance testing technologies have proliferated in parallel with the availability of the personal computer, and a wide array of tests and systems are available for which significant information regarding reliability and validity exists. The major advantages of performance testing technologies for the detection of performance impairment are the wide variety of options that are available (i.e., the face validity of performance testing can be addressed through careful selection and modification of existing performance tests), the immediate

availability of results, and the non-invasive manner in which tests can be administered (relative to biological sample testing). Disadvantages include the lack of specificity with regard to test results (i.e., many factors can alter test performance), and the cost of technology development and implementation. The high costs of performance testing technology development and implementation stem, in part, from a lack of information regarding the optimal use of performance tests in occupational settings. In addition, while the reliability and validity of performance tests have been repeatedly demonstrated in controlled laboratory settings, little evidence regarding the reliability and validity of these procedures in applied settings has been published in peer-reviewed journals. As such, the utility of these procedures has not been clearly established.

The focus of this chapter is on issues associated with the use of performance testing technologies for the detection of drug-induced impairment. Since performance tests are not selectively sensitive to the effects of drugs, alone, discussion will focus on the detection of the effects of risk factors, including drug use, sleep deprivation, or adverse physical or mental health, on performance. It is important to note, however, that while this chapter specifically addresses performance testing as a means of impairment detection, no direct or implied recommendation for exclusive development of performance testing technologies for impairment testing is suggested. It is likely that no single technology will be universally effective in all settings or situations. A combination of technologies, based on the availability of resources needed to support those technologies, will likely enhance the effectiveness of any impairment testing system.^{1,6}

4.2.2 Issues in the Selection and Implementation of Performance Testing Technologies

The presence of risk factors, such as adverse physical and emotional health, use of behaviorally active drugs/medication, and sleep deprivation, may compromise performance safety and productivity. However, the presence of such risk factors may or may not have implications for how an individual will perform his or her work. An important consideration in the selection of an impairment testing technology is the purpose for which such testing is intended.⁷ Impairment testing can be designed to detect the influence of risk factors on performance, regardless of whether or not the effects are related to the individual's work performance. However, impairment testing can also be designed to detect deviations from optimal work performance, regardless of the presence or absence of risk factors.

While the presence of risk factors may or may not have a direct effect on job performance under normal day-to-day operating conditions, it is often assumed that these factors can have an adverse impact on an individual's performance when there is a change from the normal conditions associated with job performance (e.g., the ability to respond safely and effectively to an emergency). If so, the detection of any change in normal performance (e.g., altered performance during a computerized assessment task) signals a change in an individual's capacity that could have adverse implications for job performance. If detection of risk factors is the objective of impairment testing, finding a technology that is reliable and sensitive to many risk factors may be a useful strategy, and concerns regarding reliability and validity in this pursuit become of paramount importance.

On the other hand, detection of the effects of risk factors on performance may have little to say about the likelihood with which an individual will effectively perform an appointed task. From this perspective, risk factors are relevant only if they have adverse effects on normal job performance (i.e., job performance is the relevant metric for impairment testing, not performance on assessment tasks). If the objective of impairment testing is to assess the normal job performance, considerations of the relationship between performance during impairment testing and job performance become a primary concern, and criterion validity issues must be carefully considered. Job simulation tests, such as video-disc simulators for emergency rooms,⁸ are examples of performance tests designed to maximize the assessment of on-the-job performance.² One advantage of this approach is that employees more easily accept and comply with impairment testing when the ecological or face

validity of the testing procedures is apparent.⁹ On the other hand, the development costs of simulations can be substantial.

Although it is important to decide on the purpose(s) for performance impairment testing, practical issues must also be considered. Several reviews of practical considerations associated with the selection and implementation of impairment testing technologies have been published, and many details may be obtained from these sources.^{4,9-11} However, one primary consideration is the manner in which performance tests will be administered. Performance assessment measures can be administered by trained observers, such as is the common practice with law enforcement personnel who administer field sobriety tests designed to detect the influence of drugs on driving ability, by computers under standardized conditions, or by some combination of these two approaches. The use of trained observers to administer performance impairment tests provides maximum flexibility and minimizes the amount of training and practice required of the test population. However, there are no well-validated observation systems that are currently available, and the reliability of testers will always be a concern, unless reliability and validity assessment can be incorporated into the standard testing protocol. In addition, the recurring personnel costs associated with such testing procedures can be substantial, given the need for repeated test administration.

Automation provides a solution for many of the concerns associated with trained observers. When trained observers are not available, time for testing is limited, or immediate results are needed, automated performance test administration procedures should be considered. It is also possible to standardize the presentation of stimulus materials and data collection with automated testing devices, thereby enhancing the reliability of the testing procedure. Initial development and start-up costs, which are based on the number of testing sites required and the amount of back-up support that is needed, can be substantial, but other than maintenance are not recurring costs. However, clinical interpretation of test results is limited when testing is completely automated and evaluations are based strictly on algorithms that are established as part of the testing system. Even the most automated systems will benefit from human interface for maintenance and set-up support, in addition to data management and interpretation. Given the clear advantages with regard to cost and efficiency, this chapter focuses on automated performance testing technologies.

4.2.2.1 Selecting a Performance Testing System

When selecting a performance testing system, issues that could affect the practicality, accuracy, and general utility of the system include the specific performance tests that are included in the system, the availability of norms upon which performance can be evaluated (and upon which decisions regarding readiness to perform are based), the reliability and validity of the measures, the accuracy of the measurement, the user interface, and the administrative interface. The relevance of each of these issues is discussed, as are some of the specific questions that merit some consideration when evaluating performance testing systems.

Selection of Individual Tests

Performance on various tests is thought to reflect the involvement of selective, and in some cases, isolated dimensions of human capacity, such as sensory and motor ability, attention, and elements of cognition (Heishman and Myers, Chapter 4.1). Drug effects have also been shown to vary as a function of behavioral mechanisms sustaining performance, including reinforcement contingencies and stimulus context. The use of multiple tests sampling a wide variety of human capacities under a variety of conditions has proved most effective for differentiating among the effects of drugs on behavior.¹² A general description of individual tests is beyond the scope of this chapter, but such descriptions are available elsewhere.^{4,12,13} It is important to note that the task parameters and behavioral mechanisms can vary among similar tests when used in different assess-

ment systems; it is critical to consider these variables when interpreting the dimensions of performance being measured within an assessment system.

Sensory tests measure ability to differentiate between objects varying along a stimulus dimension, such as auditory or visual intensity or frequency, or light flicker rate. The critical flicker frequency test is a commonly used type of sensory test.

Motor ability tests focus on measures associated with motor control. The most common examples of motor tasks are finger tapping tests, tracking tests, and hand steadiness tests.

Attention tests include tests of focused attention, in which performance is measured for short durations (typically less than 10 min); selective attention, which involve responding to selected stimuli among a variety of distracting or irrelevant stimuli; divided attention, which require attention to two or more tasks presented simultaneously; and sustained attention, in which some aspect of the previous three measures of attention are required over longer durations (typically 10 min or longer). Focused attention tests include measures of simple and choice reaction time, pursuit tracking, symbol substitution, encoding/decoding, time estimation, continuous performance (i.e., vigilance), visual monitoring, sequence comparisons, and visual monitoring. Clearly, performance on these tasks includes both sensory and motor components. Selective attention tasks include the Stroop test, Neisser tests, letter and number cancellation tests, dichotic listening tests, and switching or shifting attention tests.

Cognitive tests focus on measures of acquisition, memory, other performance that demonstrates effective use of language and logic, and measures of self-control or inhibition. Acquisition tests include serial and repeated acquisition, and associative learning. Memory tests include immediate and delayed free-recall and recognition tests, matching-to-sample and Sternberg tests, pattern comparison, sequence memory, selective reminding, text memory, the misplaced objects test, facial memory, and digit-span (i.e., digit-recall) or character-recall tests. Other language- or logic-based cognitive performance tests include spatial rotation, pattern matching, the Manikin test, logical reasoning, mental arithmetic, linguistic processing, vocabulary, and the Raven Progressive Matrices test. Measures of self-control include the card-perseveration and Stop/Go tests.

These tests have been used frequently for detection of the effects of risk factors on human performance. The greater the number of tests used in a system, the more comprehensive the assessment, and the more likely it will be that the adverse effects of any risk factor are detected. However, the cost of testing (i.e., test-taking time and training) is also directly related to the number of tests that are included. Many of these tests can be modified to simulate more carefully work-related activities (e.g., digit-recall tasks can be reformulated as telephone number-recall tasks) or incorporated into simulation tasks. Performance impairment test systems use varying combinations of these and other tests; however, there is no commonly agreed-upon strategy for selecting the number or diversity of tasks that are used in a test system. Selection of a system, or collection of tests, must be related to the needs of the testing organization and to the objectives of impairment testing.

Reliability and Validity

The selection of performance impairment test systems should also include a thorough consideration of the reliability and validity of the systems. Reliability refers to the consistency of results on the test across repeated testing, and validity refers to the effectiveness with which the test accomplishes its intended purpose, be that identification of the effects of risk factors or the detection of individuals who are at risk for reduced safety and/or productivity in the workplace.

Many performance impairment test systems are based on face validity, or the degree to which the tests appear to accomplish their intended purposes. While face validity is an important consideration with regard to the acceptance of a testing system by management and the workforce, it is, by itself, insufficient for demonstrating the evidence needed to ensure that the test system is indeed accomplishing its intended purposes. Few commercially available performance impairment systems provide adequate evidence of validity, and the evidence that is provided is often limited by the

context under which the evidence was collected (i.e., does not generalize to different worksites — ecological validity). It is advised that information regarding the validity of performance testing systems be collected in a proactive manner when the systems are introduced, as there is not sufficient information available to justify even global statements regarding the validity of performance impairment testing systems at the present time.

Evaluation Norms

Another important consideration in the selection of an impairment testing system is whether norm-based decision criteria will be used to evaluate readiness to perform an assignment, and if so, whether such norms are currently available. It is important that such norms address both *decrements* and *improvements* in performance, as improved performance may also signal the influence of a risk factor. For example, stimulant medications may have minimal effect on performance of most tasks, but under test conditions requiring sustained attention, enhanced performance may be noted.¹⁴ These same doses of stimulant medication may have important implications for more complex dimensions of human behavior,^{15,16} so the detection of enhanced performance may signal an increased risk for detrimental effects on other more complex behaviors that are not directly measured during testing.

Two approaches to the establishment of norms have been proposed.¹¹ The first approach stresses the development of standards of performance that are universally applied to all individuals, and evaluation of test performance is based on whether an individual performs above or below a given standard. The second approach utilizes the results of prior performance of an individual to establish a baseline upon which to evaluate future performance.

The use of a fixed performance standard has appeal in that simple and consistent criteria may be uniformly applied to all individuals who are taking the test. If these criteria are closely linked with minimal standards of successful work performance, both workers and management can easily recognize and accept the utility of the testing procedure. However, a number of shortcomings with this strategy are also apparent. There are substantial individual differences in performance on most tests, and the routine performance of some individuals may fall below the standard criterion, regardless of risk factors. In addition, performance on tests may change over time, for example, through normal aging processes. An individual who has routinely met performance standards may, over time, exhibit gradually decreasing levels of proficiency that may eventually result in substandard performance. If standardized criteria are used, legal issues associated with discrimination must also be considered,⁹ and the inclusion of the test during initial employment evaluations is recommended. The utility of minimal performance standards also presupposes that test performance is a valid indicator of effective work performance (as opposed to a valid indicator of the effect of a risk factor). The evidence needed to support such a supposition is rarely available. Under such conditions, the potential for misuse or abuse of performance test results must be considered.

Change from an individual's own baseline as determined by past performance is the more commonly used criterion for evaluation of the effects of risk factors on performance. Performance measures from previous tests can be evaluated with standardized algorithms to establish objective criteria for evaluating an individual's current or future performance on the same tests under similar test conditions. However, even when baseline measures are used, the establishment of criteria upon which to make decisions regarding whether changes from baseline performance are clinically relevant are oftentimes arbitrary. For example, if a user routinely completed 5.5 trials per minute during a test, what degree of change would be needed to be certain that the performance was influenced by some risk factor, rather than the result of chance variation in normal performance? Individualized variability criteria, which take into account a user's "normal" variance in performance, can be computed, as well, and used as a standard by which to evaluate change from baseline. The efficacy of this approach, however, presupposes that the user will provide samples of performance that are independent of the presence of any risk factor during baseline determinations; if

baselines are established while an individual is using drugs, for example, the performance of the individual under the influence of a drug will become the norm. Additional research is needed to establish strategies for the development of effective standards of performance evaluation.¹⁷

Another complication of the baseline approach concerns the interpretation of relative performance among users. It is quite possible, when using baseline criteria, that the identification of a clinically significant decrement in performance from the normal baseline of one user may occur under conditions in which the level of performance of that user is higher than the performance of another user who is performing at baseline level. Interpretation of changes from baseline is a complicated process, and few standards are currently available.

One issue that is routinely associated with the degree of acceptability of testing programs to the workforce is the consequence of poor performance on a test.⁹⁻¹¹ The establishment of policies regarding the response of management to test failures requires careful consideration. Trice and Steele⁹ suggest that coordination between performance testing and employee assistance programs will enhance the utility of both resources in the overall effort to reduce drug use by the workforce, and will enhance the acceptability of programs to both management and the workforce.

Questions have been raised about the feasibility of establishing evaluation norms that can be used across different populations and settings, or with similar tests used on different computer test systems. Certainly, situational factors influence performance on computerized performance tests. In addition, epidemiological factors, such as gender and age, have been demonstrated to influence performance on these tests. Due to mechanical and electronic differences across computer systems, as well as differences in software control techniques, it is perhaps impossible to provide norms that can be used across differing testing platforms. No universally accepted norms for the evaluation of task performance are currently available, and it is highly recommended that a scheduled evaluation of the validity of existing norms be planned in a proactive manner whenever these existing norms are used in new setting.

Administrative Interface

The ease and flexibility of the use of performance impairment test systems can be influenced by the interface between the software and test administrator. Characteristics that might be considered include the flexibility in organizing the tests to be delivered, making changes in test parameters, and in the manner in which data are presented, analyzed, and stored for future access.

Another consideration with regard to the administrative interface, as discussed previously, is the degree to which test delivery can be automated. The need for an administrator to be on site for test delivery has cost and efficiency implications. If the test is completely automated, procedures for maintaining accurate identification regarding test sessions (e.g., participant I.D., date, time, etc.) must be established.

User Interface

The cost of test delivery can also be influenced by the availability of user interfaces. The user interface can provide access to a variety of support resources to the user, including general instructions and support during training. If an instruction module is available, it should be designed to provide clear, complete, and standardized information and instructions concerning the operation of the test equipment and the completion of task components. One useful feature of an instruction module would be the inclusion of a section designed to assess whether users understood the instructions, particularly if these instructions are important determinants of user performance. This can be accomplished with a series of questions designed to provide additional information when users do not answer questions accurately. The training module should be designed to administer the tests and to provide feedback to users in a manner that enhances the development of stable and reliable performance.

4.2.2.2 Testing Platform

Hardware considerations for automated performance testing systems generally include the computer, software, monitor, and input devices. These features can be provided on multiple testing platforms, including personal computers, handheld personal digital assistants, Internet-based systems, or on platforms that are specially designed to simulate occupational contexts.

Personal Computers

Many government and commercial impairment testing systems can be implemented on standard commercially available personal computer platforms (e.g., PC, Macintosh). Despite software and hardware advancements that have minimized the differences across platforms, it is still important to consider carefully the hardware and software requirements needed to support a system, as these specifications may have important implications for the accuracy of stimulus presentation and the precision of performance measures. In addition, there may be differential costs associated with the hardware and software specifications. The speed of the computer processor is one important specification that requires careful consideration. Other concerns include the amount of memory that is needed to present the test and record the results, the manner in which the data are to be stored, the size and portability of the computer, and the video-display requirements. Some systems may also require additional components, such as joysticks, keyboards, mouse, touch-sensitive monitors, light pens and drawing boards, or response panels.

In general, the processor speeds and memory capacities of modern personal computers are sufficient to support most systems (e.g., milliseconds timing resolution and response monitoring requirements). However, running these systems on older computers having a slower processing speed and limited memory capacity could have a detrimental impact on the accuracy of the test, so caution is recommended.

There are a number of advantages associated with the use of personal computers for supporting performance testing systems. Given the ubiquity of personal computers, personal computers afford a fair amount of flexibility for equipment support and maintenance. If new equipment is acquired, personal computers can support a variety of services when not needed for performance testing. Finally, the availability of numerous personal computer vendors helps to assure reasonable prices and adequate product availability.

There are also some disadvantages associated with the use of personal computers. Desktop computers have limited mobility. Portable personal computers are typically more expensive, have more limited capabilities than desktop machines, and present greater security concerns. Data management can be more complicated if results from different testing occasions are required in a central database or if an individual is tested in multiple settings with different computers.

Handheld Personal Digital Assistants

Rapid advances in software and electronic capabilities of personal digital assistants have supported the proliferation of handheld data collection technologies.^{18,19} Since these devices are typically less expensive than personal computers, the use of handheld personal digital assistants (PDA) for performance testing reduces the equipment cost of these systems. Like personal computers, these devices can support a variety of services when not needed for performance testing, particularly if each user is provided with his or her own device. The portability of the devices permits testing to occur in a greater variety of contexts and times, thereby enhancing the flexibility and reducing the cost of data collection.

There are disadvantages to the use of handheld devices, as well. Most importantly, the video display and response input capabilities of these devices are much more limited than for personal computers. Stimulus and response requirements are critical elements of many tasks, and as such,

PDAs may limit the range of tasks that can be included in a performance testing system. Security concerns are even greater than those presented by portable computers, and data management can be an even greater challenge than with personal computers, given the limitations in data exchange options associated with these devices.

Web-Based Systems

Although not yet available, it is likely that Web-based performance testing systems will become available in the near future. Web-based systems will permit selected tasks to be presented on computers equipped with appropriate Web browser software. Hardware requirements include internet access and appropriate memory and software to support Web-based applications. Depending on the design of the Web-based system, it could be possible to tailor the specific tasks presented for the performance testing system from a menu of options. Alternatively, testing systems consisting of a standardized array of tasks can also be chosen. As such, the start-up costs of Web-based systems should be lower than with personal or handheld computer systems. Subject identification, date, and time can be recorded at the start of a test, and data from multiple subjects and test occasions can be stored in a central file for easy access to the data.

There are some clear disadvantages associated with Web-based systems, as well. The most important limitation is that the flexibility of the performance test systems is necessarily restricted to the range of tasks and associated parameters that are available through the Web-based software. While individualized software could be requested, it is likely that there will be additional time and monetary costs associated with each request. Second, stimulus presentation and response inputs may be variable across test sites unless standardized systems are used to access the Web-based software. It may also be difficult to use standardized norms to evaluate task performance, due to variable stimulus and response conditions that may exist across test sites. Finally, although the start-up costs may be reduced, there will be greater recurrent costs associated with repeated use of the Web-based software.

4.2.2.3 Test Implementation

In addition to considerations of impairment testing systems and the equipment and platform to administer the systems, the implementation of the testing system must also be considered. Test cost, frequency of administration, maintenance of stable patterns of performance (i.e., motivation), and worker acceptance are among the issues that merit consideration.¹¹ In addition, concerns regarding the legal status of performance test systems, the manner in which labor unions and arbitrators might view such test systems, and whether or not there is a potential for misuse of the test system could affect system implementation.⁹

Cost

Test costs include the initial expense of acquiring the test equipment and providing a test space, the time required to complete the test, and administrative costs (e.g., record keeping, test set-up, maintenance and replacement of equipment). However, test costs may be complicated by the presence of hidden factors, as well.¹⁰ For example, cost of training the users may be substantial. Based on the consequences of test failure, lost work time may also be factored in, particularly under conditions in which the false positive rate (i.e., identification of the influence of a risk factor on a user's performance when none, in fact, exists) is high. There are additional costs associated with initial negotiations between management and workers concerning the appropriateness of a testing program and the consequences of test failure, and potential costs associated with litigation, should it occur.

Test Frequency

No clear landmarks exist for making decisions regarding test frequency. In general, tests are administered before an individual begins an assigned work activity. However, risk factors can emerge at any time, and are not limited to activities that occur before work activities begin. For example, the effects of fatigue, illness, and drug use can all occur after work has begun, and would not be measured by tests occurring only at the beginning of a work activity. In addition, it is not clear whether the frequency of test administration influences the reliability of test performance. If tests are administered on a regular basis, or if rest intervals (e.g., weekends) separate successive tests, motivational changes may influence performance.

Maintenance of Performance Stability

Repeated administration of tests, without contingencies designed to maintain motivation, invariably result in decrements in performance over time. Considerations of the maintenance of motivated performance across repeated administration of a test is an important consideration during the implementation of an impairment testing system. It is generally assumed that under conditions in which access to assigned work activities, and financial compensation for that work, is contingent on suitable test performance, motivated performance is likely to be maintained across repeated testing.¹⁰ However, there have not been adequate investigations of this assumption, and it is likely that emotional behavior would also occur if access to work were denied as a result of poor performance on a test. The use of additional contingencies that target performance stability might be helpful, in addition to the seemingly punitive consequence of loss of work opportunities associated with poor performance. It has been suggested that the use of more complex or varied testing procedures may also help eliminate changes in motivation over time. Clearly, additional research on these issues is needed.

User Acceptance

Another important consideration with regard to the implementation of an impairment testing system is the acceptance of the test system by the workforce. Worker acceptance is influenced by the comfort in taking the tests, as well as by test relevance, or face validity, availability, and accuracy.¹¹ Comfort refers to the degree to which worker performance on these tests is acceptable under routine testing conditions, and may be inversely related to the likelihood of false positive outcomes. Relevance, or face validity, is associated with the extent to which workers report that performance during the test will reflect performance of their assigned work tasks. Availability refers to the reliability of the test equipment — if the tests cannot be administered when scheduled, confidence in the accuracy of the test system is questioned. Accuracy refers to the extent to which the test results are related to risk factors. Workers receive direct or indirect feedback on test systems (i.e., pass or fail). Rates of false positives (failures given the absence of any risk factor) and false negatives (passes given worker recognition of the influence of a potential risk factor, such as drug use) influence worker estimates of test accuracy.

Legal Issues

No clear guidelines exist with regard to the legal status of performance impairment test systems. In comparison with employee selection criteria, Trice and Steele⁹ suggest that the legality of these test systems may be related to the degree to which their use results in discriminatory outcomes. They cite Klein's²⁰ description of an 80% rule as a workable strategy for assessing discriminatory practices. If the pass rate obtained when testing of any race, sex, or ethnic group is less than 80% of the group with the highest pass rate, then the test system has an adverse impact. Trice and Steele⁹

also indicate that the absence of information regarding a cause of test failure could have a negative impact on considerations of the legality of test systems, because under such conditions employees might feel unduly compelled to reveal details of their personal lives.

The status of performance impairment test systems with regard to fair-labor practices is also undetermined at the present time. Trice and Steele⁹ suggest that since biological sample testing approaches to the detection of drug use have been ruled in the past to be a mandatory labor practice, and as such, require bargaining with labor or unions prior to implementation, performance test systems would likely be viewed in a similar manner. However, they also note that, because performance tests are less invasive than biological sample testing procedures, and can be demonstrated to have greater job relatedness, employers could make the case that performance impairment test systems can be implemented unilaterally without bargaining.

Potential for Misuse of Test Systems

Misuse of performance impairment tests is related to the consequences of worker performance. Test systems can be implemented with the sole purpose of providing feedback to workers regarding their level of performance (i.e., no consequences associated with work activities are imposed). The objective of such testing procedures is to provide workers with information to use to adjust their own on-work and off-work behavior in an attempt to more accurately monitor their own levels of safety and productivity. For example, in describing a feasibility study of the implementation of a performance testing system, truck drivers adjusted their own rest behavior based on feedback they received during performance testing, even though that feedback was unrelated to drivers' work eligibility.²¹ On the other hand, systems that use the results of performance on impairment tests to influence work eligibility (and possibly employment status) are more likely to involve some risk for test misuse.

No clear guidelines exist for the appropriate use of performance impairment test systems for work eligibility. There is general agreement that in situations in which worker or public safety is potentially influenced by a worker's performance, impairment test systems are justified. However, no clear criteria for identifying safety issues are available.⁹ The use of such tests as a means of managing worker productivity is less universally accepted, and if used as an employee evaluation criterion, such tests should be given careful scrutiny.

4.2.3 Applications of Impairment Testing Technologies

Currently, application of laboratory-based performance assessment technologies occurs in at least three settings. The most frequent utilization of this technology is in the law-enforcement setting. Law enforcement personnel have varying amounts of training and experience in the administration of performance tests and in the interpretation of the behavior of individuals during test performance. In addition, law enforcement personnel have limited opportunities to compare their own evaluations of performance on field sobriety tests with the results of drug assays from blood tests taken concurrently with the tests in order to monitor the accuracy of their evaluations. Under these conditions, the reliability and validity of the field sobriety test remain largely unknown, in spite of its widespread utilization. Results from recent assessments of the reliability and validity of performance-based drug evaluation programs, such as sobriety testing, are presented here.

A second application of laboratory-based performance assessment technologies has been in the field of fitness-for-duty assessment, primarily supported by military and other government agencies. A varied number of fitness-for-duty assessment batteries have been developed; several of these are reviewed here. A major strength of these fitness-for-duty assessment batteries is the availability of a substantial database on the reliability and validity with which these batteries can detect changes in performance related to a number of manipulations, including drug administration, sleep deprivation, and exposure to extreme environments.

A third application of laboratory-based performance assessment technologies has been in the field of readiness-to-perform assessment in workplace settings. Many of the approaches to readiness-to-perform assessment that are being used in workplace settings have evolved from strategies that are currently in use in government-sponsored performance assessment batteries or laboratory settings, but, in general, these approaches have been subjected to reliability and validity assessment with less consistency. Several assessment technologies that have been subjected to some reliability and validity assessment are described here.

4.2.3.1 Law Enforcement Applications: Drug Evaluation and Classification Program

Background

Motor vehicle accidents are the leading cause of death in the U.S. for people aged 1 to 34.²² Studies investigating the prevalence rate of drugs other than alcohol in fatally injured drivers have reported varied results, ranging from 6 to 37%.^{23–27} Among individuals stopped for reckless driving who were judged to be clinically intoxicated, urine drug testing indicated 85% were positive for cannabinoids, cocaine metabolites, or both.²⁸ These relatively high prevalence rates reinforce the general assumption that psychoactive drugs are capable of impairing driving,^{29,30} although drug prevalence rates do not imply impaired driving.^{31,32} Because certain drugs reliably degrade psychomotor and cognitive performance in the laboratory (Heishman and Myers, Chapter 4.1), many drug-related vehicular accidents and DUI/DWI arrests probably involve impaired behaviors critical for safe driving.

Currently, the only standardized procedure for detecting drug-induced impairment is the Drug Evaluation and Classification (DEC) program,³³ which is used by police departments throughout the nation. The DEC program consists of a standardized evaluation conducted by a trained police officer (Drug Recognition Examiner, DRE) and the toxicological analysis of a biological specimen. The evaluation involves a breath alcohol test, examination of the suspect's appearance, behavior, eye movement, and nystagmus, field sobriety tests, vital signs, and questioning of the suspect. From the evaluation, the DRE concludes (1) if the suspect is behaviorally impaired such that he or she is unable to operate a motor vehicle safely, (2) if the impairment is drug-related, and (3) the drug class(es) likely causing the impairment. The toxicological analysis either confirms or refutes the DRE's drug class opinion.

Several field studies have indicated that DREs' opinions were confirmed by toxicological analysis in 74 to 92% of cases when DREs concluded suspects were impaired.^{17,34–38} These studies attest to the validity of the DEC program as a measurement of drug-induced behavioral impairment in the field. However, the validity of the DEC evaluation has not been rigorously examined under controlled laboratory conditions. Heishman, Singleton, and Crouch^{39,40} have examined the validity of the individual measures of the DEC evaluation in predicting whether research volunteers were administered various drugs of abuse. A synopsis of these studies is presented.

Method

Research volunteers were recruited from the community. Before the study, participants were given psychological and physical examinations to determine whether they were healthy and capable of participating in the study. At each test session, a single drug dose or placebo was administered under double-blind conditions. Sessions were separated by 48 to 72 h. In Study 1, participants received oral ethanol (0, 0.28, 0.52 g/kg); intranasal cocaine (4, 48, 96 mg/70 kg); and smoked marijuana (0, 1.75, 3.55% ⁹-tetrahydrocannabinol [THC], 16 puffs). In Study 2, participants received oral alprazolam (0, 1, 2 mg); oral D-amphetamine (0, 12.5, 25 mg); codeine (0, 60, 120 mg); and smoked marijuana (0, 3.58% THC, 8 puffs). Dosing of the various drugs was staggered so that the DEC evaluation occurred during peak drug effect.

The DEC evaluation began with an ethanol breath test. DREs measured pulse and recorded information about physical defects, corrective lenses, appearance of the eyes, and visual impairment. DREs also assessed eye tracking and nystagmus, pupillary size, and condition of eyelids. The next segment involved examination of the eyes and performance of four field sobriety tests (FST). Subjects' eyes were tested for horizontal gaze nystagmus, vertical nystagmus, and convergence. The FST were Romberg Balance (RB), Walk and Turn (WT), One Leg Stand (OLS), and Finger to Nose (FN). The RB assessed body sway and tremor while subjects stood for 30 s with feet together, arms at sides, head tilted back, and eyes closed. The WT test required subjects to take nine heel-to-toe steps along a straight line marked on the floor, turn, and return with nine heel-to-toe steps. The OLS assessed balance by having subjects stand on one leg, with the other leg elevated in a stiff-leg manner 15 cm off the floor for 30 s. Subjects were given a brief rest between right and left leg testing. In the FN test, subjects stood as in the RB and brought the tip of the index finger of the left or right hand (as instructed) directly to the tip of the nose. DREs then measured pulse, blood pressure, and oral temperature.

The final portion involved further examination of the eyes. DREs estimated the diameter of each pupil to the nearest 0.5 mm under conditions of ambient room light, nearly total darkness, indirect light, and direct light. While illuminating the eyes under direct light from a penlight for 15 s, DREs assessed constriction of the pupils and fluctuation of pupillary diameter. Last, DREs measured pulse and assessed muscle tone, attitude, coordination, speech, breath odor, and facial appearance.

Results

The 76 variables derived from the DEC evaluation were first analyzed using stepwise discriminant analysis to determine the variables that best predicted the presence or absence of each drug. This subset of best-predictor variables was then subjected to a discriminant function analysis that predicted and classified whether subjects were dosed or not dosed with drug. The resulting data were classified as true positive, true negative, false positive, or false negative. These parameters were then used to calculate several measures of predictive accuracy of the DEC evaluation, including sensitivity, specificity, and efficiency.

In Study 1, the stepwise discriminant analysis resulted in a subset of 17 variables that were the best predictors of ethanol. The discriminant function comprising these 17 variables predicted the presence or absence of ethanol with extremely high accuracy. The model was equally accurate in predicting the presence (sensitivity = 94.4%) and absence of ethanol (specificity = 92.6%); overall predictive efficiency was 93.3%. The analysis also resulted in a subset of 17 variables that were the best predictors of dosing with cocaine. The discriminant function predicted the presence or absence of cocaine with high accuracy. The model had greater specificity (96.3%) than sensitivity (88.9%), and efficiency was 93.3%. The stepwise discriminant analysis resulted in a subset of 28 variables that best predicted the presence or absence of marijuana. The discriminant function comprising these 28 variables predicted the presence (sensitivity = 100%) and absence (specificity = 98.1%) of marijuana with extremely high accuracy; predictive efficiency was 98.8%.

In Study 2, the stepwise discriminant analysis resulted in a subset of seven variables that were the best predictors of alprazolam. The model was more accurate in predicting the absence of alprazolam (specificity = 96.7%) than its presence (sensitivity = 78.3%), and predictive efficiency was 90.4%. The analysis resulted in a subset of three variables that were the best predictors of dosing with D-amphetamine. As with alprazolam, the model's predictions had greater specificity (92.5%) than sensitivity (75.0%), and efficiency of the model was high (86.5%). The discriminant analysis resulted in a subset of two variables that were the best predictors of codeine. The model's predictions had much greater specificity (92.4%) than sensitivity (34.8%), and efficiency was moderate (73.2%). The discriminant analysis resulted in a subset of seven variables that were the best predictors of marijuana. The model predicted with greater accuracy the absence (specificity = 93.3%) of marijuana than its presence (sensitivity = 61.4%); predictive efficiency was 82.7%.

Conclusion

The validity of the DEC evaluation was examined by developing mathematical models based on discriminant functions that identified the subsets of variables that best predicted whether subjects were dosed with placebo or active drug. The data clearly indicated that a subset of variables of the DEC evaluation accurately predicted acute administration of various psychoactive drugs across several pharmacological classes, including alprazolam, D-amphetamine, marijuana, ethanol, cocaine, and to a lesser extent, codeine. These findings suggest that predictions of impairment and drug use may be refined if DREs focused on a subset of variables associated with each drug class, rather than the entire DEC evaluation.

4.2.3.2 Government Application: Tests of Fitness for Duty

Background

Much of the early interest in the area of human performance testing was funded and manned by several branches of the U.S. Military. The successful military mission depends on optimal performance by its personnel. Hostile and hazardous environments may have subtle to profound influences on a soldier's performance.⁴¹ The goal of military human performance research was to identify those environments and agents that cause a deterioration in ability, and to what degree. With this knowledge, military personnel could attempt to compensate for, or avoid, undesirable environments or agents. A comprehensive review of many assessment batteries used by government agencies, which includes a review of evidence related to the reliability and validity of the batteries, can be found elsewhere.^{4,7}

Computerized Performance Test Batteries

Most government-sponsored computerized performance test batteries are compilations of computer performance tests that were originally developed and tested in controlled laboratory settings. The purpose of many of these tests is to determine the effects of risk factors on fitness for government duty, and to assess the efficacy of countermeasures designed to offset the performance effects of these risk factors.

Unified Tri-Service Cognitive Performance Assessment Battery — The Unified Tri-Service Cognitive Performance Assessment Battery (UTC-PAB) was constructed by the Tri-Service Working Group on Drug Dependent Degradation of Military Performance, which eventually became known as the Office of Military Performance Assessment Technology (OMPAT).⁴² OMPAT, which was headed by Fred Hegge, included representatives from the U.S. Navy, Air Force, and Army. The group developed a standardized laboratory tool to assess cognitive performance using repeated measures in a tri-service chemical-defense biomedical drug-screening program.⁴³ All the tasks in the test battery were designed to run on standard MS DOS platform computers with graphical presentation and keyboard responding.

The UTC-PAB is a library of cognitive tests that can be modified into smaller subsets or batteries for a specific purpose. The original UTC-PAB consisted of 25 tasks that were chosen due to their construct validity, reliability, and sensitivity to levels of cognitive functioning. Several of the commonly known subsets or variations include the Testor's Workbench/Automated Neuropsychological Assessment Metrics (TWB/ANAM) or (ANAM) battery, the Naval Medical Research Institute Performance Assessment Battery (NMRI-PAB), the UTC-PAB/NATO AGARD STRES Battery, and the Criterion Task Set (CTS).⁴³

The UTC-PAB's modular design offered the investigator the freedom of customized batteries by combining any number of the tasks, and in any order. This enabled researchers to utilize only

those tasks that best suited the needs of each protocol or evaluation. Accuracy and response time were automatically measured and the data collection updated for any of the tasks that were selected. Numerous parameters of the individual tasks could be modified such as stimulus duration; inter-trial interval; number of stimulus presentations; and length of the task. Instruction screens and help files could be modified as well. The default parameter settings for the UTC-PAB tasks were patterned from the North Atlantic Treaty Organization AGARD-STRES Battery.⁴⁴

Table 4.2.1 contains the individual tasks of the UTC-PAB. These tasks measure a variety of human cognitive and psychomotor functioning, including focused attention, selective attention, divided attention, memory, and a variety of additional task components.^{4,7}

Walter Reed Army Institute Performance Assessment Battery — The Walter Reed Army Institute Performance Assessment Battery (WRPAB) was designed by Dr. David Thorne, Fred Hegge, and colleagues at the Walter Reed Army Institute of Research, Division of Neuropsychiatry, Department of Behavioral Biology. This battery was also supported by OMPAT, but was designed to measure changes in performance over time as a function of acute perturbations (e.g., drugs, fatigue, sleep deprivation) as opposed to serving as a screening tool.⁴⁵

The WRPAB was designed to offer investigators a menu of individual cognitive, perceptual, and psychomotor tests from which investigators could choose specific tests to best support a given

application. Table 4.2.2 lists the individual tasks of the WRPAB. These tasks assess focused attention, selective attention, acquisition, memory, and a variety of additional task components.⁴⁵ A user-friendly building routine allows for the development of smaller, individualized PABs. Options are available to adjust the software to match the testing equipment and for specifying the characteristics of the data output, and individual task parameters can be adjusted by using documentation that accompanies the software. The software operates on the MS DOS platform with graphic screen presentation on a local or remote monitor with responding performed on a standard keyboard.⁴⁵ Installation of a timer card may be necessary to ensure precise timing.

As mentioned earlier, the WRPAB is best suited for experiments with repeated measures designs involving treatments, dosages, or differing environments. Specific tasks in the WRPAB have been found to be sensitive to certain psychoactive drugs. Several government agencies have implemented the WRPAB as a research tool. For example, the National Institute on Drug Abuse Intramural Research Program has studied the effects of nicotine and nicotine replacement on smokers' and nonsmokers' cognitive abilities and attention processes using the Two-^{46,47} and Six-Letter Search.⁴⁶ Cognitive abilities were also measured using the WRPAB Digit Recall and Logical Reasoning tasks.^{46,47}

Naval Medical Research Institute Performance Assessment Battery — The Naval Medical Research Institute Performance Assessment Battery (NMRI-PAB) was developed to measure the effects of a wide variety of military environments upon the technically oriented tasks of Marine and Naval personnel. The battery's methodology was based on a tri-service methodology in an attempt to standardize measurement of human performance in military environments.⁴¹ The NMRI-PAB, like the WRPAB and UTC-PAB, is a menu-driven, microcomputer-based assessment tool that comprises individual tasks.

The NMRI-PAB consists of eight individual tasks that measure different aspects of human functioning (Table 4.2.3). The software controller allows the experimenter to modify certain aspects

of task presentation. The software collects detailed information about subject's accuracy and speed of responding. Since the NMRI-PAB is microcomputer based, multiple subjects can participate simultaneously and in different locations. The software runs on standard MS DOS platform with graphical screen presentation and keyboard responding. The design of this assessment tool allows for repeated measures testing. The individual tasks of the NMRI-PAB measure the following areas of human cognitive functioning, including focused attention, selective attention, memory, and a variety of additional task components.⁴

Advisory Group for Aerospace Research and Development—Standardized Test for Research with Environmental Stressors Battery — The Advisory Group for Aerospace Research and Development—Standardized Test for Research with Environmental Stressors Battery (AGARD-STRES) was developed to investigate the effects of environmental stress on human performance.⁴⁴ After receiving funding from the U.S. Air Force, the Advisory Group for Aerospace Research and Development (AGARD) set out to construct a standardized performance assessment battery using tests that had proved successful in stress research. The group utilized seven of the individual tests from the UTC-PAB.⁴⁴ The AGARD-STRES battery was designed to provide a standardized method of task presentation (e.g., the seven tests are presented in a predetermined order, and the task parameters are designed to remain constant) in order to more effectively compare performance on these tasks across subject populations and settings. The software runs on standard MS DOS platform with graphical screen presentation with keyboard input. This would facilitate standardization and allow researchers to compare all administrations of the battery equally. This assessment tool is well suited for repeated measures research.

Table 4.2.4 presents the individual tests of the AGARD-STRESS battery. Focused attention, divided attention, and memory categories of tasks are included in this battery, in addition to a variety of other tasks.

Automated Neuropsychological Assessment Metrics — The Automated Neuropsychological Assessment Metrics assessment battery (ANAM) is a modified version of the AGARD STRES battery. The ANAM was developed primarily as a screening tool for assessing neuropsychological functioning and has been used in military and commercial aviation applications. This battery has added pursuit tracking, which requires a mouse for completion, and has eliminated tracking, dual task, and reaction time tasks from the AGARD STRES battery because these tasks engendered

unsuitably variable performance. A tracking test, running memory test, the Walter Reed mood scale, and the Stanford sleepiness scale were substituted.

Table 4.2.5 presents the various tasks of the ANAM battery assess. Focused attention and memory categories of tasks are included in this battery, as well as a variety of additional task components.

The Spaceflight Cognitive Assessment Tool (S-CAT) is a variant of the ANAM that was compiled by NASA's Behavioral Health and Performance Group (BHPG) to assist in behavioral monitoring and assessment of flight crew health.⁴⁸ The battery was designed to assess memory, sustained concentration, working memory, and recall and was developed for use aboard the Space Station Mir and the International Space Station, as well as to support future prolonged space missions.

Another variant is the ANAM Readiness Evaluation System (ARES), a multiple-user cognitive testing system designed to run on PDAs using the Palm OS.⁴⁹ This system also incorporates many of the features of the ANAM. ARES is shipped with three standard test batteries. The NeuroCog battery is primarily used for monitoring the recovery of individuals with CNS damage. It is designed for use by neuropsychologists with ANAM interpretation experience. The ARES Commander is a self-monitoring battery that assesses concentration, working memory, and mental efficiency. The ARES Warrior is designed as a neurocognitive screening tool, which can be used by medical personnel during field operations. Custom batteries can also be created with provided support software.⁴⁹

Vocabulary

Neurobehavioral Evaluation System 2 — The Neurobehavioral Evaluation System 2 (NES2) is a neurobehavioral evaluation system designed to facilitate screening of populations at risk of nervous system damage due to environmental agents. This evaluation system is administered on a microcomputer. Epidemiologic research influenced the sets of tests that were included in this battery. An expert committee convened by the World Health Organization (WHO) and the National Institute for Occupational Safety and Health (NIOSH) proposed a set of core tests for this battery. Many of the core tests that were chosen are adaptations of preexisting clinical instruments that have been recognized as valuable tools in investigating neurotoxin exposure.⁵⁰

Table 4.2.6 presents the individual tests of the NES2 battery. Motor ability, focused attention, selective attention, acquisition, and memory categories of tasks are included in this battery, in addition to a variety of other tasks. The battery is made up of separate tasks; performance on combinations of these tasks is potentially altered by exposure to neurotoxic agents such as pesticides, solvents, or carbon monoxide. Many of the tasks are suitable for repeated testing of any individual. Five of the tests are similar to the core tests of the WHO battery.⁵⁰

The NES2 software was developed using IBM Advanced BASIC. The software is menu-driven and allows the interviewer to choose the individual tasks that are presented at any one session. The software was designed to run on IBM PC-compatible hardware with a standard DOS operating system. Response inputs occur through a joystick with a pair of push-buttons.⁵⁰

Baker and colleagues⁵⁰ found that the validity and stability of three tests in the NES2 were comparable to five previously validated traditional interviewer-administered neuropsychological instruments. High correlations were reported between individual trials of the same interviewer-administered task. Stability on four of the computerized tests was supported by high correlations between scores when research subjects were tested on four separate days.

Automated Portable Test System — The Performance Evaluation Tests for Environmental Research Program (PETER), jointly sponsored by the U.S. Navy and NASA, attempted to identify measures of human cognitive, perceptual, and motor abilities that would be sensitive to environmental perturbations that are associated with decrements in safety and productivity. An extensive collection of literature yielded more than 140 tests that were rated for reliability and sensitivity. The PETER Program incorporated those tasks that were most suitable for repeated-measures applications. Inclusion criteria were met if a task's inter-trial correlations were unchanging and variances were homogenous across baselines.⁵¹

The Automated Portable Test System (APTS) evaluation system is an outgrowth of the work of the PETER Program. The PETER program had identified tests that were reliable, stable, and sensitive to environmental and toxic stressors. Kennedy and his colleagues⁵² adopted and computerized a core set of 18 tasks from the PETER Program's recommended list of performance tasks suitable for repeated measures application. Those tasks are listed in Table 4.2.7.

The APTS was designed for portability works on IBM PC compatible systems running on a standard MS DOS operating system.⁵³ The battery measures abilities of motor function, focused attention, selective attention, acquisition, and memory, as well as spatial perception and reasoning, mathematical calculation, and other language skills.^{4,7} Similar to most of the computerized performance assessment batteries, additions and deletions of individual components have occurred as the battery has matured and been used in different applications.

Memory Assessment Clinics Battery — The Memory Assessment Clinics Battery (MAC) was designed to assess the effects of pharmacological treatments on simulated memory tasks.⁵⁴ Intended to study potentially cognitive-enhancing pharmaceutical compounds, the battery is also used to assess age-related memory differences in ongoing clinical trials. Initial testing of the MAC Battery was administered on an AT&T 6300 computer utilizing color graphic presentation, laser-disk technology, and touch-screen responding along with other custom-made manipulanda.

The battery mimics real-life memory and recognition demands, such as remembering a 7- or 10-digit telephone number, or associating a name with a face. Table 4.2.8 presents the individual tasks of the MAC battery. Focused attention, divided attention, acquisition, and memory categories of tasks are included in this battery.

Synwork — Many performance batteries involve the administration of varied tasks, each of which requires the focused application of a limited number of cognitive or motor skills, in a sequential manner. One concern that has repeatedly been raised regarding the use of sequential laboratory tests as a system for measuring performance impairment is that such systems do not assess all human capabilities, including some that are critically dependent for job performance. For example, while performance tests may assess specific abilities, such as reaction time, or learning ability, it may be unusual in job settings for such activities to be required in a sequential manner. Elsmore and colleagues⁵⁵ contend that real-world human behaviors or operations may consist of two or more of these attributes and abilities occurring concurrently. Effective job performance may require the ability to engage in multiple tasks in a simultaneous or continuous manner, adjusting between task requirements as priorities change. It is unclear whether such higher-order performance requirements are effectively assessed in sequential performance test systems.

In contrast to PAB-like tasks involving the sequential presentation of individual performance tasks, Synwork attempts to emulate the simultaneous or continuous task demands of real-world jobs by requiring subjects to perform four individual tasks presented concurrently in one of four quadrants of a screen.⁵⁵ The tasks are presented on a standard IBM PC compatible computer with DOS operating platform. Subjects interact with the software by manipulating a standard mouse.

The individual tasks of the Synwork software measure attention and working memory (Sternberg Memory Task); mathematical calculations (Arithmetic task); spatial perception and reasoning (Visual Monitoring); and auditory perception and reasoning (Auditory Monitoring). A more detailed account of the Synwork software can be found in Elsmore et al.⁵⁶

Elsmore and colleagues,⁵⁵ while examining the impairing effects of sleep deprivation, demonstrated that subjects find Synwork to be more interesting and demanding than a sequentially administered PAB-like version, but performance engendered by Synwork is less sensitive to the effects of sleep deprivation than the same tasks presented simultaneously.

Psychomotor Vigilance Task — The Walter Reed Army Institute of Research's Department of Behavioral Biology has developed a field-deployable version of a commercial Psychomotor Vigilance Task (PVT) that has been widely used in sleep research. The software runs on handheld PDAs running the Palm Operating System (Palm OS). It is modeled after the simple reaction time task of Wilkinson and Houghton,⁵⁷ as modified by Dinges and Powell.⁵⁸ The Palm OS version incorporates additional stimulus, feedback, control, and data options developed by Dr. Thorne. In laboratory studies, performance on the PDA task has been shown to be sensitive to time-on-task fatigue effects, sleep deprivation, and circadian variation.¹⁸ Field studies have utilized the PVT to measure the efficacy of caffeine gum as a sleep loss countermeasure.

MiniCog — A Palm OS-based cognitive testing system, called MiniCog, is currently under development by the National Space Biomedical Research Institute's (NSBRI) neurobehavioral and psychosocial factors team. It will contain cognitive tasks that assess attention, (vigilance, divided attention, and filtering), motor control, verbal and spatial working memory, and verbal and spatial reasoning. The development team has designed this testing system for both spaceflight and ground-based research. MiniCog project development is currently obtaining norms from healthy subjects in a laboratory setting.¹⁹

4.2.3.3 Occupational Application: Readiness To Perform Tests

Background

Given the complex nature of many commercial work environments, as well as the reciprocal interactions between employers and employees, factors associated with the development and implementation of performance impairment test systems in commercial environments become equally complex. In addition to the selection of test systems that are reliable and valid indicators of performance impairment, it is equally important to consider issues associated with worker acceptance of the testing system, time associated with the test, and the economic implications of use and non-use of impairment test systems. Substantial research into the use of impairment testing systems has been conducted over the past decade; however, the vast majority of this work is available only in company reports and/or technical monographs; with few exceptions (e.g., Delta), little information is available in peer-reviewed scientific publications.

Performance Tests in Applied Settings

Four applications of laboratory-based performance impairment test systems are described. These systems have been chosen to be presented for two reasons. First, they provide examples of the use of test systems for the measurement of performance impairment in commercial settings. Second, some information regarding the reliability and validity of these systems is available.

NovaScan, Nova Technology, Inc. — The NovaScan is a testing paradigm, rather than a fixed performance test, in that the system represents a method of presenting selected tests in a manner

that standardizes the attentional requirements of the test user. The paradigm also allows for measurement of elements of attention allocation. The testing paradigm is designed to present any combination of a subset of 30 individual tasks originally developed and validated through the UTC-PAB project, described above. The tasks that are presented can be selected based on the specific needs of the test application (e.g., different combinations of tests have been used for different commercial applications, based on the specific needs/interests of the company employing the NovaScan). The resulting test system is designed to assess a variety of job-related skills, as well as generic attentional processes associated with the completion of the tasks, in a time-efficient manner.

The NovaScan is presented on a PC-compatible computer equipped with standard memory and visual capabilities, and is run on a DOS-based operating system. A customized response apparatus, including a joystick, control keys, and a keypad, is recommended. Trials of the tasks chosen to be included in the test system are displayed on the computer monitor in a random manner, thereby eliminating the need for the user to focus attention among simultaneously presented tests. However, divided attention components can be added, if needed. The length of the test (i.e., number of trials presented) can be adjusted based on the demands of the test environment. Performance is evaluated in an automated fashion using a change-from-baseline approach, and the test can be administered in an automated or supervisor-controlled manner.

The NovaScan has received substantial testing in a number of laboratory and applied settings. Performance on the NovaScan has been demonstrated to be sensitive to the effects of alcohol, marijuana, diazepam, amphetamine, scopolamine, and an over-the-counter antihistamine.^{6,59,60} In addition, epidemiological differences in performance associated with gender, age, and occupation has been considered. Variations of the testing paradigm have been used in a number of commercial settings.

Delta, Essex Corporation — Delta, a commercial performance impairment testing system produced by the Essex Corporation, was derived from the Automated Portable Test System (APTS) evaluation system, which, in turn, was based on the work of the Performance Evaluation Tests for Environmental Research Program (PETER), a jointly sponsored U.S. Navy and NASA program designed to identify measures of human cognitive, perceptual, and motor abilities that would be sensitive to environmental perturbations that are associated with decrements in safety and productivity.

The Delta system contains many of the same tests contained in the APTS system, including those that monitor motor function, reaction time, attention and working memory, learning and memory, spatial perception and reasoning, mathematical calculation, and language (Table 4.2.1). More complete descriptions of the psychometric and validity studies supporting the utility of this testing system are available elsewhere.^{61,62}

Performance on the Delta system has been demonstrated to be sensitive to the effects of alcohol, amphetamine, scopolamine, chemoradiotherapy, and hypoxia.^{63–66} The Delta test system has been used in a number of applied settings, including airplane and tank operator training sites.^{61,62}

Performance-on-Line, SEDInc — Performance-on-Line is a software-based cognitive and psychomotor divided-attention task designed to evaluate tunnel vision, a rapid change in visual system activity in response to stress, that at elevated levels is associated with driving risk.⁶⁷ The task was derived from the hardware-based Simulated Evaluation of Driver Impairment (SEDI) distributed by SEDInc. SEDI was found to generate performance that was highly reliable and sensitive to the effects of alcohol and marijuana.^{68,69} SEDI used numeric displays that were novel to some subjects, and the memory-intensive instructions were found to be difficult to remember for some individuals. The hardware-based SEDI was also costly, and subjects frequently reported eye-muscle fatigue after its use.⁷⁰

The Performance-on-Line software was designed to include language-free graphics and instructions that were not memory-intensive. Central and peripheral targets that are presented simultaneously require independent visual discrimination and responding. The software is designed to run

on any computer using a DOS operating system. It supports a color graphic display and utilizes keyboard response inputs. The test is self administered, provides on-screen instructions, and has five independent levels of difficulty. An administrative interface allows for parametric modifications, such as whether or not performance feedback is provided to participants. The data are stored in formatted files that allow for easy use with other commercial spreadsheet or data analysis programs.⁷⁰ The Performance-on-Line software predicts driving performance⁷¹ and engenders behavior that is sensitive to the effects of sleep deprivation, alcohol, and other drugs.⁷²

CogScreen-Aeromedical Edition — In the late 1980s the Federal Aviation Administration (FAA) supported the development of a computer-based cognitive screening tool, CogScreen.⁴ The goal of the FAA was to create a testing system that was sensitive to changes in cognitive function. If left unnoticed, cognitive dysfunction may result in poor pilot judgment or slow reaction time in critical operational situations.⁷³ Several phases of task selection and normative data collection yielded a cognitive testing system comprised of 11 tasks.⁴ The current version, CogScreen-Aeromedical Edition (CogScreen-AE), is used during the medical re-certification evaluation of aviators suspected and/or known to have neurological or psychiatric conditions. This cognitive testing system detects changes in attention, immediate- and short-term memory, visual perceptual functions, sequencing functions, logical problem solving, calculation skills, reaction time, simultaneous information processing abilities, and executive functions.

4.2.3.4 Occupational Applications: Simulation

Background

An occupational simulation is a representation that approximates the actual operating conditions of a job.² Different scenarios can be used to represent specific sets of conditions developed for the purpose of assessing discrete sets of occupational skills within specified contexts.⁷⁴ Although initially developed for training purposes, they have evolved as tools for assessing skills for educational or formal certification purposes and are being used more frequently for evaluating occupational fitness. Simulation has most often been used to evaluate workers' ability to use machinery or drive vehicles. It has been more challenging to assess the job performance of other professionals, such as lawyers, doctors, and managers, with computer-based simulation, because their tasks are varied and complex. Recent developments in the use of actors in defined roles have expanded the use of simulation in a broader array of professions.

In those cases where simulation is possible, it can offer some important advantages. Simulation allows participants to perform job functions under a range of circumstances without risk of injury or adverse economic consequences. For example, within a given scenario, it is possible to monitor performance within contexts that approach or reach catastrophe (e.g., pilot response to problems during flight; account representative management of competition). Safety is an important attribute of simulation. A second advantage of simulation is that it permits the repeated assessment with specified scenarios, thereby supporting the assessment of reliability. High reliability is a necessary attribute for any effective performance assessment method, a threat when assessment is conducted in natural settings. A third advantage is that simulation can provide consistency in assessment procedures, which, in turn, allows for the comparison of performance across individuals or across worksites when individuals or groups are measured repeatedly over time. A simulated assessment exercise can also be recorded and played back. This provides an opportunity for participants to repeatedly observe their own performance within the context of a given scenario. Another advantage of simulation is that it supports assessment in rare or unusual contexts. The true measure of an employee may lie in performance during the low-probability real-world conditions with major safety or economic implications. Simulation provides a means to evaluate performance in low-probability but significant contexts. A final advantage of simulation is that the complexity and difficulty can

be systematically altered within a given scenario. Employee ability to maintain effectiveness and efficiency as complications escalate is an important measure of performance capacity.

There are important limitations to simulation that deserve consideration, as well. As with all assessment strategies, validity should be questioned. Clearly, performance assessment that takes place in the occupational setting while work is actually performed is the most valid approach. Simulations can make employees feel as if they are operating under normal conditions; however, it is also clear that job performance expressed in a simulator is not “real.” With regard to capturing the workplace context, simulators are still superior to computerized performance batteries. Nonetheless, performance assessment using computerized batteries can offer a greater degree of control over contextual variables that can influence performance, and can provide more precise measurement of specific functions, such as cognition, reaction time, divided attention, and memory, than is possible during simulation. Simulation provides a gross measure of overall job performance, whereas computerized batteries offer precise assessment of more elementary dimensions of performance. As simulators try to incorporate key elements of the workplace context, they become vulnerable to unknown confounding due to these contextual representations.

Simulations in Experimental Settings

Howland and colleagues⁷⁵ used maritime simulators that replicated merchant ship operation to test the effects of low-dose alcohol exposure in two separate scenarios. Maritime cadets were randomly assigned to receive either 0.00 (placebo) or 0.04 g% blood alcohol concentration, or BAC (a relatively low dose equivalent to two to three commercial cocktails). Significant alcohol-induced impairment was observed on simulated power plant operation and piloting.⁷⁶ The testing of simulated ship operation the day after random dosing at 0.10 g% BAC (five or more commercial cocktails) is ongoing. These experimental studies using a single occupational model are consistent with the adverse associations of heavy alcohol use derived from large-scale cross-sectional surveys of worker performance.⁷⁷ Simulation picked up subtle effects of low-dose alcohol sedation on work performance that are not visible in surveys. Furthermore, the merchant ship experiments could not have been conducted ethically without the use of simulators.

Automobile and truck simulators have also been used in randomized studies to demonstrate the impairing effects of various doses of alcohol.^{78–80} Similar studies have been conducted using flight simulators.^{81–85} In addition, both types of simulators have been used to assess the effects of marijuana, nicotine, and other sedative medications.^{86–88} Simulations have also been used to examine other environmental perturbations, including sleep deprivation and elevated carbon dioxide levels.^{89,90}

4.2.4 Conclusion

This chapter focused on issues associated with the use of performance testing technologies for the detection of performance impairment. While the application of this technology remains largely untested, the evidence presented in this chapter strongly suggests that this technology shows promise as a component of performance impairment testing systems. A substantial database regarding the reliability and validity of performance tests for measuring the effects of risk factors on human performance has been established, and initial efforts at developing performance testing systems made effective use of this database. Limitations with regard to the predictive validity of these tests continue to be addressed in modifications to existing testing systems, as well in the development of more sophisticated simulation testing systems. Issues regarding the selection and implementation of performance testing systems have been addressed in recent publications.^{4,9–11} Clearly, careful and systematic evaluations of the use of these systems in applied settings is warranted.

It is important to note, however, that while this chapter specifically addressed performance testing as means of impairment detection, there is no evidence to suggest that performance testing systems are more effective than other impairment testing systems. Trice and Steele⁹ suggest that

performance testing systems may have practical advantages over more common biological sample testing systems, including potentially being more widely accepted by the workforce, requiring less invasive testing requirements, and interfacing more efficiently with existing employee assistance programs, but no evidence to support such claims is available, due to the limited information regarding the use of these systems. It is likely that no single technology will be universally effective in all settings, or even on one setting across all individuals over time. The combination of technologies, based on the availability of resources needed to support those technologies, will likely enhance the effectiveness of any impairment testing system.

Acknowledgment

Mr. Taylor and Dr. Heishman were supported by the NIH Intramural Research Program, NIDA.

4.3 PUPILLOMETRY AND EYE TRACKING AS PREDICTIVE MEASURES OF DRUG ABUSE

Wallace B. Pickworth, Ph.D.¹ and Rudy Murillo, B.A.²

¹ Battelle Centers for Public Health Research and Evaluation, Baltimore, Maryland

² Clinical Pharmacology and Therapeutics Branch, National Institute on Drug Abuse, National Institutes of Health, Department of Health and Human Services, Baltimore, Maryland

4.3.1 Introduction

Measurements of pupillary diameter, eye tracking, and the pupillary response to a flash of light are readily available, non-invasive indices of central nervous system function. Recently, such

parameters have been used by law enforcement personnel, employers, and primary care and emergency room physicians to make a rapid and initial assessment of recent drug ingestion. In this chapter, the physiological basis for the control of pupil size and the light reflex and the instruments used to measure pupillary responses are briefly reviewed. The results of a residential, within-subject study of the effects of various drugs of abuse on pupillary size and the light reflex are described. A summary of the literature on the effects of abused drugs on pupillary measures is given. An outpatient study analyzing the effects of polydrug use on pupillary responses is also presented. The advent of new classes of pupillometers that measure eye position and gaze is also included. These new instruments hold great promise for revealing subjective effects of drugs and drug withdrawal through a psychophysiologic measure. The chapter concludes with a discussion of the utility and limitations of pupillometry in the detection of abused drugs.

4.3.2 Physiological Basis of Pupil Size and the Light Reflex

4.3.2.1 Pupil Size

The human pupil ranges in diameter from 1.5 mm at full miosis to 8.0 mm at full mydriasis. The most powerful determinant of pupil size is the ambient light level. Pupil size is also influenced by several factors including subject age, iris pigmentation, gender, state of arousal, and time of day.¹ Newborns have very small pupils because the pupillary dilator muscle develops well after birth. Pupil size is maximal during adolescence and decreases in older age. People with a lightly pigmented iris (blue eyes) generally have larger pupils than those with a heavily pigmented iris (brown eyes). Pupil diameter tends to decrease over the course of the day.² About 17% of the population have pupils of unequal size (anisocoria), but differences exceeding 0.5 mm occur in only about 4% of the population.

4.3.2.2 Instrumentation

Pupil size can be estimated from direct observation. A variety of cards and scales are available whereby the experimenter compares the size of the pupil to standard patterns and scales. The simplest and most often used card is the Haab pupil gauge. This consists of a card with black circles graduated in size between 2 and 10 mm in 0.5 mm increments. The card is held on the temporal side of the eye out of the subject's vision (to reduce accommodation miosis). Pupil size can be determined to an accuracy of 0.2 mm. A disadvantage of this method is the inability to make measurements in the dark and the possibility that the subject's eyes will react to the test or its administration.

The Polaroid close-up camera has been used to photograph the eye of subjects before and after the administration of opiates and other psychoactive drugs.^{3,4} Pupil size can be estimated to within 0.1 mm by means of calipers and a magnified scale that is concomitantly photographed. Disadvantages of this method are the possibility that the flash used in the photography can reduce pupil size, the expense of the film, and the possibility that the subject may focus on the camera, thereby inducing accommodation miosis. Recently, digital cameras have been used to determine pupil size.⁵

Sequential photographs can be used to monitor pupil size over an extended time. If the pupil is illuminated with infrared light and infrared sensitive film is used, recordings can be made in total darkness. Although this method was used in seminal studies of the pupillary light reflex and other dynamic applications,^{6,7} it is seldom used today because of the high cost of film, processing time, and limited temporal resolution.

Other pupillometers usually employ infrared illumination of the eye and a television or computer. These instruments sample pupil diameter at rates up to 60 images per second. Pupillometers offer the advantage of accurate sampling across a wide range of ambient light. They can record pupil diameter over extended times, enabling the investigator to quantify dynamic aspects of the

light reflex and fluctuations of pupil size (hippus). These instruments are extensively used to determine the effects of drugs, fatigue, stress, autonomic reactivity, and level of anesthesia. Instruments produced by Eye Dynamics (Torrance, CA) and Pulse Medical Instruments (Bethesda, MD) use short programmed trials to evaluate pupil diameter, light reflex measures, and saccadic or smooth pursuit eye tracking.

Modern pupillometers have the added ability to track eye position and movement. Pupillometers such as the I-Portal (Neuro Kinetics, Inc, Pittsburgh, PA), the Eye Link II (SR Research, Ontario, CA), and the EyeTrace 300X (Applied Science Laboratories, Bedford, MA) have sampling speeds of up to 600 samples/second. Their ability to track eye position and gaze fixation enables these pupillometers to be used to study components of drug abuse, such as drug seeking, stimulus relevance, and cue reactivity, which cannot be assessed with conventional pupillometry. One experiment of particular interest would be to study the time it takes drug users to find illicit drugs or drug paraphernalia within a matrix of control objects using eye tracking technology. In the following section aspects of the pupillary light reflex measured with modern pupillometers are discussed.

4.3.2.3 Light Reflex

When the retinal rods and cones are stimulated with light in the visual wavelength, there is constriction of the pupil. A major factor in determining the intensity of the reflex is the adaptation state of the retina because the rate of change of retinal illumination evokes the response. Other factors influence the light reflex. The retinal area that is stimulated is differentially sensitive; the fovea and macular areas are most sensitive and the periphery is least sensitive. The subject's state of arousal⁸ and anxiety⁹ and the wavelength of the stimulus light and its direction all may influence the reflex.^{10,11}

As shown in Figure 4.3.1, there are several components of the light reflex that may be evaluated with dynamic pupillometers. From studies in cats, monkeys, and rabbits, Lowenstein and Lowenfeld¹² identified the components of the light reflex that were controlled by parasympathetic and sympathetic innervation of the smooth muscles controlling pupil diameter. They concluded that the parasympathetic nervous system must be intact to observe the light reflex; the sympathetic nervous system influences the shape of the reflex. For example, in the absence of sympathetic innervation, the constriction velocity is increased and the dilation velocity is decreased. Conversely, in situations of increased sympathetic tone, the constriction is sluggish and incomplete, and the pupil slowly returns to its baseline size. The effects of abused drugs on these and other components of the light reflex were studied in the experiment described below.

Figure 4.3.1 Pupil diameter before (A) and after a light stimulus (S). Constriction (B) and dilation (D) velocities are determined from a least square fit of the slope. Amplitude of constriction (C) represents the maximal difference in diameter before and after the flash.

4.3.3 Laboratory Study of Pupillary Effects of Abused Drugs in Humans

In an effort to understand and quantify the effects of several classes of abused drugs on human pupillary response, a study, briefly described below, was conducted on the residential unit of the Intramural Research Program of the National Institute on Drug Abuse (NIDA). Further methodological details and results are published elsewhere.¹³

4.3.3.1 Methods

Subjects

Eight healthy male subjects with a mean age of 34.1 years volunteered for this study. During their participation in the study, they resided on a clinical research unit. The subjects had extensive histories of illicit drug use that included recent ingestion (within the past 2 years) of opiates, marijuana, stimulants, alcohol, and sedative-hypnotics, although they were not dependent on any drug (except nicotine).

Study Design

All the subjects received each of the treatments. Neither the subjects nor the technician knew the identity of the treatment at the time of the experiment. The treatments were randomly presented a minimum of 48 hr apart. On study days subjects swallowed three opaque capsules, drank a large cold tonic drink (480 ml, in 15 min) with 2 ml 95% ethanol floating on top, and smoked a cigarette (either marijuana or placebo) according to a paced puffing procedure: 8 puffs per cigarette, 20 s puff retention, 40 s interpuff interval.¹⁴ On any experimental day all of the dosage forms could have been a placebo (no active drugs) or one of the dosage forms could have contained an active drug. The active drug conditions were marijuana 1.3 and 3.9% THC; ethanol 0.3 and 1.0 g/kg; hydromorphone (Dilaudid) 1 and 3 mg; pentobarbital 150 and 450 mg; and amphetamine 10 and 30 mg. Drugs were administered at the same time each day (9:45 A.M.).

Pupillary Measures

Measures of pupillary diameter and parameters of the light reflex were made using a PupilsScan (Fairville Medical Optics) handheld pupillometer.¹⁵ The sampling rate was 10 diameters (in pixels)/s; the light reflex was evoked with a 0.1-s, 20 Lumen/ft², 565 nm (green) stimulus light. Initial (prestimulus) pupil diameter and the following parameters of the light reflex were derived from the data collected on a personal computer: constriction and dilation velocities and the amplitude of constriction.^{2,16} Pupillary measures were collected from the left eye before drug administration and at 30, 105, 180, and 300 min after the drug.

Subjective Measures

Subjective effects of the experimental drugs were estimated from scores on several standardized tests and computer-delivered 100 mm visual analog scales that measured drug symptoms, “strength” and “liking.” The 100-mm scale was anchored with the terms “not at all” (0 mm) and extremely (100 mm). The subjects rated subjective effects at about the same times of the pupillary measures.

Performance Measures

Before beginning the experimental series, subjects trained to a consistent level of performance on several tests of cognitive performance including the Digit Symbol Substitution Test (DSST). In

the DSST a random digit appeared on the computer screen. The subject used the numeric keypad of the computer to reproduce a geometric pattern (three keystrokes) that was uniquely associated with the displayed digit. The dependent measure used was the number of correct responses during the two-minute task.¹⁷ In the circular lights task the subject pushed lighted buttons on a wall-mounted board. At the start of the task, one of the 33 buttons was illuminated. Pushing that button added a point to the score and lighted another button at a random position. The score was the total number of points (hits) in the 1-min task.¹⁸

Statistical Analyses

Repeated measures analyses of variance (ANOVA)¹⁹ were conducted on the pupillary, subjective, and performance variables. The main factors were drug (12 levels) and time (5 or 6 levels). Using *a priori* tests, data points after drug administration were compared to baseline values and placebo values. The pupillary effects were correlated with subjective effects (visual analog rating of “high” and “strong”) and performance effects (DSST, number correct; circular lights, hits) by means of the Pearson’s product-moment correlation.

4.3.3.2 Results

Pupillary Measures

Pupil Diameter — The experimental drugs caused significant changes in pupillary diameter measured before the presentation of the light flash (Figure 4.3.2). One-way ANOVAs on the peak change indicated significant differences among the treatment conditions. A two-way ANOVA indicated significant differences among drug conditions and time of measurement, as well as a significant drug by time interaction. As shown in Table 4.3.1, high doses of ethanol, marijuana, hydromorphone, and pentobarbital decreased pupil size, whereas amphetamine caused an increase. Although the changes were statistically significant, their magnitude was not large. Pupil size decreased by 0.7, 0.5, 1.4, and 1.0 mm after the high doses of ethanol, marijuana, hydromorphone, and pentobarbital, respectively. The maximal increase after the high dose of amphetamine averaged 0.4 mm.

Constriction Amplitude — The constriction amplitude of the light reflex differed significantly among the treatment conditions (Figure 4.3.2). A two-way ANOVA indicated significant differences among drug conditions and time of measurement, as well as a significant drug by time interaction. As summarized in Table 4.3.1, constriction amplitude was significantly decreased by high doses of ethanol, marijuana, and hydromorphone. The magnitude of the effect was small and the maximal changes occurred at the time of the maximal change in pupillary size.

Constriction Velocity — The velocity of pupillary constriction changed significantly as a function of the drug treatment (Figure 4.3.2). A two-way ANOVA indicated significant differences among drug conditions and time of measurement, as well as a significant drug by time interaction. As shown in Table 4.3.1, constriction velocity decreased after high doses of ethanol, marijuana, hydromorphone, and pentobarbital. The high doses of marijuana, hydromorphone, and pentobarbital reduced the constriction velocity by 1.2, 0.6, and 1.3 mm/s, respectively, changes that represented reductions of 26, 14, and 27% of control velocities.

Dilation Velocity — As summarized in Table 4.3.1, only the high dose of marijuana significantly changed (reduced) the velocity of dilation of the pupil during the recovery phase of the light reflex.

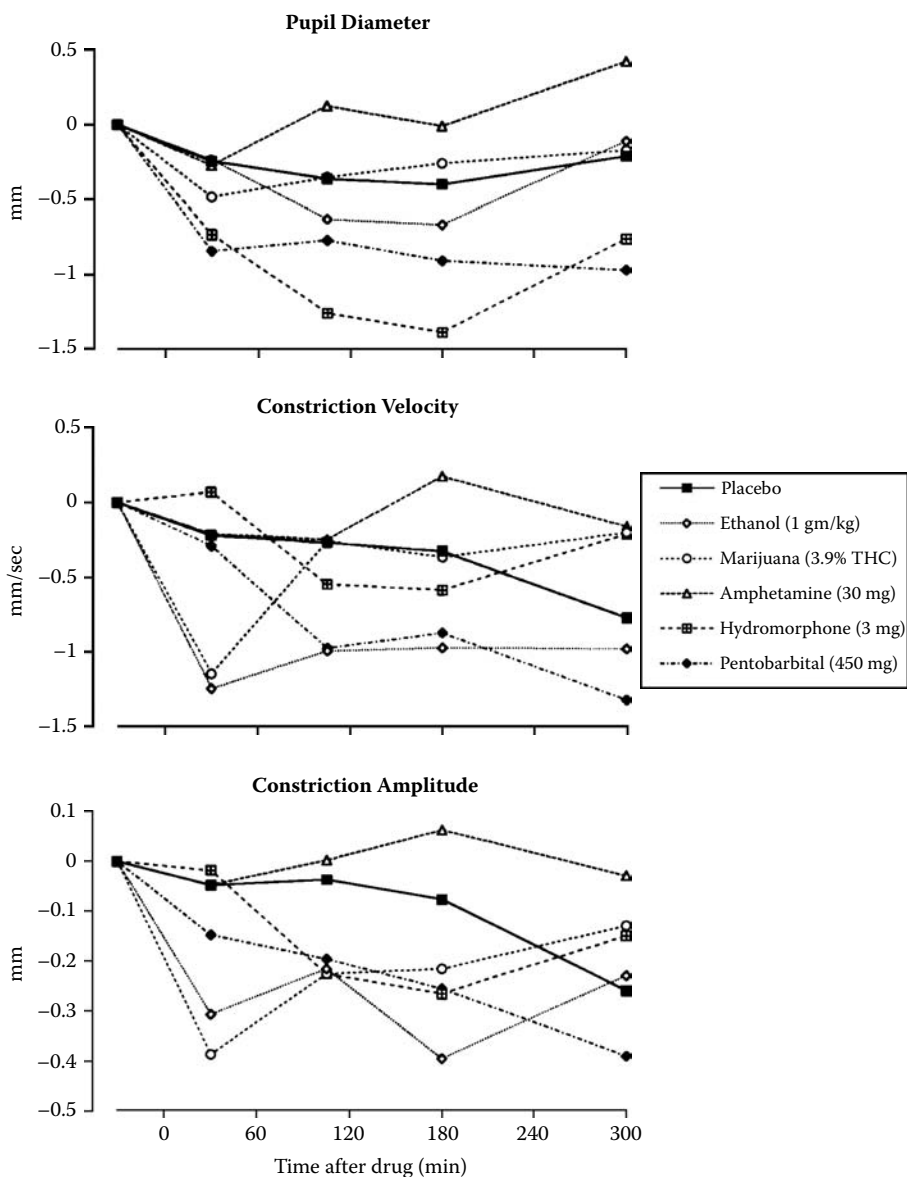

Figure 4.3.2 After high doses of the experimental drugs, changes (from baseline) in initial (prestimulus) pupil diameter, constriction velocity, and constriction amplitude varied as a function of the drug condition and time.

Subjective Measures

Visual analog scale scores on the strength of drug effect were significantly different as a function of drug condition and time of measurement (Figure 4.3.3). There was also a significant drug by time interaction (Figure 4.3.3). Similarly, scores on the drug liking visual analog scale differed significantly among the drug conditions. These data indicate the subjects perceived the high doses of the experimental drugs as being strong and being liked. The positive endorsement of questions of drug liking and strength by experienced drug users indicate that such drugs have a high abuse potential.²⁰

Table 4.3.1 Pupillary Effects of Experimental Drugs

Drug	Dose	Pupil Diameter	Constriction Amplitude	Constriction Velocity	Dilation Velocity
Ethanol	1 g/kg	↓	↓	↓	NC
Marijuana	cigarette 3.9% THC	↓	↓	↓	↓
Hydromorphone	3 mg	↓	↓	↓	NC
Pentobarbital	450 mg	↓	↓	NC	NC
Amphetamine	30 mg	↑	NC	NC	NC

Note: Arrows indicate direction of significant changes from baseline values; NC indicates there was no significant change.

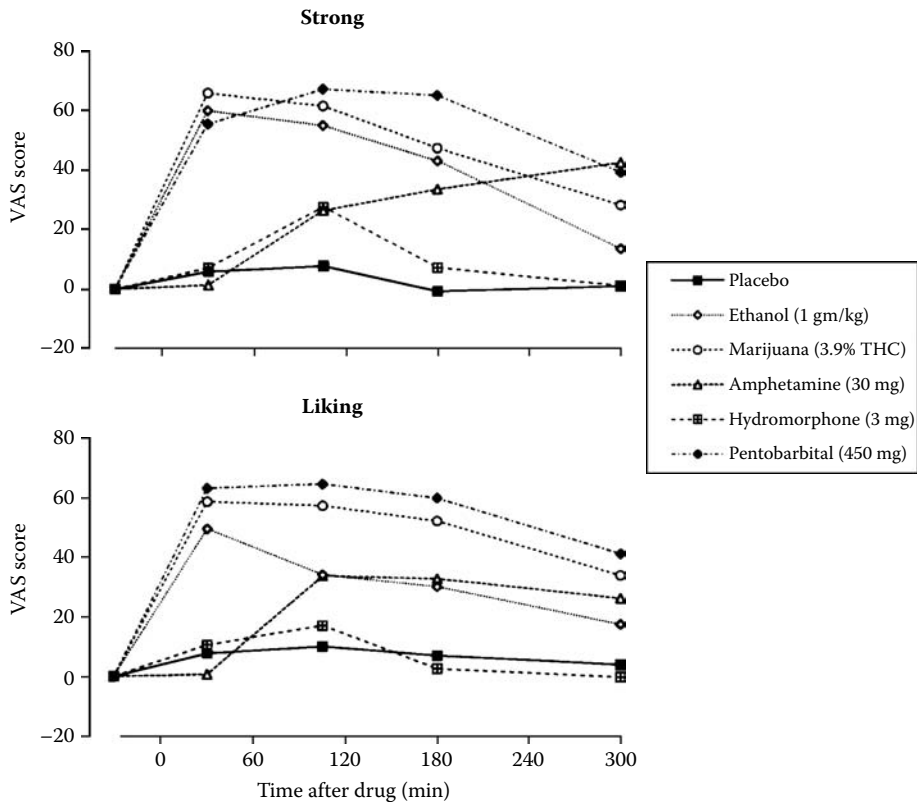

Figure 4.3.3 High doses of the experimental drugs increased scores (from baseline levels) on drug strength and drug liking. The effects varied as a function of the drug administered and the time after administration.

Performance Measures

Digit Symbol Substitution Task — ANOVAs on the number of correct responses on the DDST indicated there were significant differences among drug conditions, time of measurement, and a significant drug by time interaction (Figure 4.3.4). Performance was significantly impaired after high doses of marijuana, ethanol, pentobarbital, and hydromorphone.

Circular Lights Task — High doses of ethanol and pentobarbital significantly decreased the number of hits on the circular lights task (Figure 4.3.4). The other experimental drugs caused no significant change in this measure of performance.

Figure 4.3.4 High doses of the experimental drugs caused changes (from baseline) in performance on the circular lights and DSST tasks. The effects varied as a function of the administered drug and the time after administration.

Correlational Analyses

A visual comparison of the pupillary, subjective, and performance effects of the experimental drug (Figures 4.3.2 through 4.3.4) indicates that in most instances the maximal change in each parameter occurred at the same time. Furthermore, the time of maximal effect was related to the dosage form. For example, smoked marijuana produced maximal subjective and performance effects 30 min after drug administration, whereas the capsules (pentobarbital, hydromorphone, and amphetamine) produced significant maximal changes 120 min or longer after drug administration. Correlational analyses were performed to determine if performance and subjective changes varied as a function of pupillary change. Correlations between the change in pupil diameter and the changes in the subjective and performance measures (total of 176 correlations) were statistically significant in only 15 cases (7 at the high dose condition). Furthermore, only 3 of the significant correlations in the high dose conditions occurred during the time of the maximal pupillary change. These results indicate there is a very weak relationship among the pupillary, performance, and subjective effects of these experimental drugs. Furthermore, pupillary changes, even under ideal laboratory conditions, do not predict changes in performance of experimental tasks. However, as discussed below, changes in pupillary measures may be useful in predicting performance in the workplace environment.

4.3.4 Effects of Abused Drugs on Pupillary Measures

4.3.4.1 Opiates

In early clinical studies, it was shown that morphine caused miosis and morphine withdrawal caused mydriasis.²¹ In humans, most opiates caused pupillary constriction and diminished the

constriction and dilation velocities of the light reflex.²² The results of the above study confirm that hydromorphone, a potent orally active opiate, decreased pupil size and diminished the constriction velocity and amplitude of the light reflex. Buprenorphine, a partial opiate agonist, also decreased pupil size, constriction and dilation velocities, and the constriction amplitude of the light reflex.^{23,24} On buprenorphine withdrawal there was a significant increase in pupil size and parameters of the light reflex.¹⁶ Mixed agonists-antagonists caused less constriction than full agonists. For example, cyclazocine caused a small but reliable miotic response in human volunteers.²⁵

4.3.4.2 Stimulants

As was demonstrated in the experiment above and elsewhere, amphetamine²⁶ and its derivatives and cocaine^{26,27} significantly increased pupil size through an activation of the sympathetic nerve innervation of the iris. Evidence from an animal study indicated that amphetamine-induced mydriasis is partially mediated through actions in the brain where it inhibits the parasympathetic output of the oculomotor nucleus.²⁸ Tennant²⁹ also reported that cocaine and amphetamine-type stimulants increased pupil diameter and diminished the pupil reaction to light.

4.3.4.3 Barbiturates

In the laboratory experiment described above, pentobarbital (450 mg) caused a small but significant decrease in pupil size and a reduction in the constriction velocity of the light reflex. The maximal effect was measured 300 min after oral drug administration. Nystagmus (rhythmical oscillation of the eyeballs) and ptosis (drooping of the upper eyelid) are the eye signs that are most often attributed to ingestion of barbiturates, benzodiazepines, ethanol, and other CNS depressants.^{26,30,31}

4.3.4.4 Ethanol

As shown in the above experimental results, ethanol caused a small but significant decrease in pupil size and a reduction in the response to a flash of light. In a review of the effects of abused drugs on pupillary and ocular measures, Tennant²⁹ reported that ethanol caused no change in pupil size but diminished the light reflex. Nystagmus is a well-known sign of ethanol intoxication.²⁶

4.3.4.5 Marijuana

The high dose of marijuana decreased pupil diameter in all subjects in the experiment described above. The peak response occurred 30 min after smoking. There were significant decreases in the constriction and dilation velocities of the light reflex. Tennant²⁹ reported that marijuana obtunded the light reflex without changes in pupil size. In a subsequent study, marijuana smoking obtunded the light reflex and caused decrements in smooth pursuit eye tracking.³²

4.3.4.6 Hallucinogens

Both indoleamine (e.g., lysergic acid diethylamide, LSD; psilocybin) and phenethylamine hallucinogens (e.g., mescaline) increased pupil diameter.²⁶ There have been no systematic studies of the effects of these drugs on dynamic measures of the light reflex. Phencyclidine (PCP) does not cause marked changes in pupil size or light reflex. However, subjects intoxicated with PCP often show horizontal and vertical nystagmus.²⁶

4.3.4.7 Nicotine

Cigarette smoking has been reported to increase pupil size during the time the cigarette is being smoked.³³ Pupil size returned to baseline values within 45 s after smoking a single cigarette. Pupil diameter of smokers was smaller (mean = 5.1 mm) than that of nonsmokers (mean = 6.0 mm) suggesting that chronic cigarette smoking may persistently decrease pupil size.³⁴

4.3.4.8 Club Drugs

MDMA (3,4-methylenedioxymethamphetamine), otherwise known as “ecstasy,” causes significant mydriasis.^{35,36} Cami et al.³⁵ reported significant mydriasis (increases of 3.5 mm) in subjects given doses above 50 mg. Ketamine, also known as “Special K,” also causes mydriasis.³⁷ Other drugs such as gamma hydroxybutyrate (GHB) and flunitrazepam, Rophynol (“Roofie”) are more difficult to study using pupillometry because they tend to render the users unconscious, although flunitrazepam has been found to cause mydriasis.³⁸ More research must be done to understand more fully the pupillary effects of this relatively new class of abused drugs.

4.3.5 Pupillary Effects of Concomitant Drug Use

Although a high percentage of drug users tend to abuse more than one drug at a time, no studies had analyzed the pupillary effects of poly-drug use. In a recent study³⁹ we measured the pupillary effects of polydrug use in an outpatient population undergoing methadone treatment. The purpose of this study was to determine if pupillary changes occurred when subjects co-administered illicit drugs while they were maintained on methadone or buprenorphine.

4.3.5.1 Methods

Participants

Patients ($n = 37$) already enrolled in studies at the NIDA Archway Clinic were invited to participate. The subject population included 21 males and 16 females; 68% of the participants were African Americans and 32% were Caucasian. The average age of the participants was 41.9 years. The participants had extensive drug abuse histories that included current opioid dependence, chronic cocaine use, and frequent use of other illicit drugs. Most ($n = 35$) were maintained on methadone in doses that ranged from 70 to 100 mg/day; two participants were maintained on buprenorphine (16 mg/day).

Study Design

After agreeing to participate, and signing an informed consent form, the operation of the pupillometer, FIT 2000 (Pulse Medical Instruments (PMI), Rockville, MD), was explained and demonstrated to the research volunteers. They were allowed to practice the test sequence in the presence of the administrator until they obtained a successful test sequence. This single exposure was the only supervised orientation the participants received.

Participants used the pupillometer three occasions each week, on days when they provided a urine sample for drug testing. Urine was analyzed on-site for: amphetamines, barbiturates, benzodiazepines, cocaine, marijuana metabolites, phencyclidine, and opiates. Subjects were compensated for successful pupillary tests with a \$2 coupon redeemable at a fast food restaurant chain.

Study Measures

On study days, room lights were kept at a constant illumination. The participant stood comfortably in front of the instrument and looked through the viewing lens with one eye (left) while the other eye was open at all times. The pupillary test sequence was initiated when the participant pressed a start button. A green LED target quickly moved horizontally across the viewing screen. Saccadic velocity (SV) data were collected at a rate of 750 Hz during this phase. The target then paused in the middle of the viewing field, and a series of light flashes ensued. Initial pupillary diameter (ID) (measured before the flashes), constriction amplitude (CA), and constriction latency (CL) were collected at a rate of 60 Hz. If the instrument lost eye tracking or for any reason that data could not be collected, a low tone sounded, a fault message was given, and the test was aborted. After a fault message the participant could re-initiate a test sequence. A successful test sequence lasted about 30 s. Subjects repeated the test sequence until they obtained a successful result.

Statistical Analyses

The data were analyzed to determine the feasibility for use in this patient population. The number and percentage of successful and unsuccessful (faults) tests were summarized for each participant. Pupillary data from days when there was no evidence of other recent drug use (urine negative for abused drugs) were compared to days when there was evidence of recent drug use (urine positive). These comparisons were done using both within-subject and between-subject tests. A drug-free baseline was determined for subjects who provided negative urine on more than 10 days. The four parameters were used to determine the goodness-of-fit calculation as follows:

$$\text{Index} = \left(\frac{\mu_{\text{ID}} - \text{ID}}{\sigma_{\text{ID}}} \right)^2 + \left(\frac{\mu_{\text{CL}} - \text{CL}}{\sigma_{\text{CL}}} \right)^2 + \left(\frac{\mu_{\text{CA}} - \text{CA}}{\sigma_{\text{CA}}} \right)^2 + \left(\frac{\mu_{\text{SV}} - \text{SV}}{\sigma_{\text{SV}}} \right)^2$$

where ID, CL, CA, and SV are the value of the parameters on any particular pupillary screening, μ represents the mean baseline value, and σ is the baseline standard deviation of each parameter. After a baseline was established for each participant (FIT index), a chi square analysis with 4 degrees of freedom was calculated for subsequent drug positive days. This result was referenced against the critical chi square values table ($p < 0.1$, $\chi^2 = 7.78$, $p < 0.01$, $\chi^2 = 13.28$). These calculations yielded the probability that the particular reading differed from the established baseline. Finally, pupillary parameters in participants who always gave negative urine were compared to those who always gave positive urine to determine if there was more stability of measures among those who only ingested the treatment medication.

4.3.5.2 Results

Fault Analyses

The overall success rate for correct use of the pupillometer by participants ($n = 37$) was 92.9%; that is, nearly every time participants attempted a trial they were eventually successful. The success rate (percentage obtaining a successful sequence on the first try of each study day) in participants after minimal experience (2 weeks or about 6 exposures) was 72%, and if the four participants who had trouble obtaining stability were eliminated, the overall success rate further increased to 81%. Thus, even minimally trained patients maintained on methadone⁴ or buprenorphine,¹⁶ drugs known to produce miosis, obtained reliable pupillary measures.

Table 4.3.2 Participants ($n = 6$) with >10 days When Urine Was Positive or Negative for the Presence of Illicit Drugs

	Urine Negative	Urine Positive
Pupil diameter (ID) (mm)	5.7 ± 0.51	5.9 ± 0.68
Constriction amplitude (CA) (mm)	0.8 ± 0.12	0.8 ± 0.3
Constriction latency (CL) (mm/s)	297.9 ± 12.1	301.5 ± 14.6
Saccadic velocity (SV) (mm/s)	80.9 ± 7.22	82.8 ± 11.1

Note: Values shown are mean \pm standard deviation of the four FIT parameters.

Table 4.3.3 Comparison of Pupillary Measures in Participants ($n = 4$) with Urine Samples Consistently Negative for Illicit Drugs and Participants ($n = 20$) with Consistently Positive Urines

	Urine Negative	Urine Positive
Pupil diameter (ID) (mm)	5.2 ± 0.31	5.9 ± 0.81
Constriction amplitude (CA) (mm)	0.9 ± 0.14	0.7 ± 0.13
Constriction latency (CL) (ms)	301.2 ± 9.86	314 ± 22.9
Saccadic velocity (SV)(mm/s)	75.0 ± 6.46	76.0 ± 10.1

Note: Values shown are mean \pm standard deviation of the four FIT parameters.

Pupillary Reactions on Drug-Positive and Drug-Negative Days

Shown in Table 4.3.2 are the mean and standard deviation of the four parameters collected on subjects ($n = 6$) on days (minimum of 10) when their urine was negative for drugs of abuse compared to days when their urine was positive for abused drugs. Although the mean values are similar, the variability increased (larger standard deviation) for ID, CL, and SV on urine-positive days. The variability in the measures obtained for constriction amplitude was similar regardless of the presence of illicit drugs in the urine.

Comparison of Individuals Always Positive or Negative for Illicit Drugs

Many of the participants ($n = 20$) were never able to provide ten or more drug-free urine samples, and a few ($n = 4$) always gave urine samples that were drug negative. The data from these subjects were not useful for the comparisons illustrated in Table 4.3.2, but examination of the variation of the parameters in Table 4.3.3 revealed a similar pattern. Specifically, the standard deviation of the mean of ID, SV, and CL was larger in the group with the positive urine samples.

Fit Equation

Participants with 10 or more clean days were analyzed using the FIT equation. A baseline was established from pupillary data on days when the urine was negative for illicit drugs. The pupillary measures from days when the urine was positive for drugs were inserted into the FIT equation to determine probabilities between $p < 0.1$ and $p < 0.01$. For example, one participant had baseline values of $5.35 (\pm 0.68)$, $0.97 (\pm 0.12)$, $281.52 (\pm 8.0)$, and $78.2 (\pm 9.8)$ for ID, CA, CL, and SV, respectively. On a day when the urine was positive for cocaine and methamphetamines, the values for the four parameters were 6.31, 0.79, 305.1, and 91.23. When inserted into the equation this generated a FIT index of 14.69, a value well above the critical values for the $p < 0.1$ (7.78) and $p < 0.01$ (13.28). Using this methodology, concomitant drug use was detected 29% of the time at the $p < 0.1$ level. There was a high variability of detection among participants. At the p 0.1 level,

drug positive urines were detected 53% of the time on three participants. However, in another three participants, detection averaged only 10%.

4.3.6 Utility and Limitations of Pupillary Testing for Abused Drugs

In some circumstances the use of pupillometry in drug detection appears reasonable. However, based on the experimental evidence cited above and a review of the literature, there are reservations about the use of pupillometry to detect recent ingestion of abused drugs. Several areas of concern and the limitations of the methodology are discussed below.

4.3.6.1 Subject Variability

The size of the pupil and its responsiveness to a light stimulus vary considerably across subjects. Normal pupil diameter ranges between 2 and 8 mm in the extremes of ambient light. In conditions of controlled, low-level (4 ft cd) ambient light, pupil size ranged from 3.5 to 8 mm, and there were similarly large variations in constriction and dilation velocities of the light reflex.² Fosnaugh et al.² recorded pupil measures on 4 consecutive days and found very little within-subject variation in pupil size and parameters of the light reflex. These findings have practical and theoretical importance. The wide variability between subjects indicates that a single examination of the pupils and the light reflex is unlikely to be highly predictive of recent drug ingestion. On the other hand, the small within-subject, day-to-day variability indicates that a relatively small change in pupil measures in an individual may be an indicator of recent drug ingestion. These suggestions emphasize the importance of having verifiable, drug-free baseline data (both mean and variation is important) for individuals enrolled in testing programs. As demonstrated in the polydrug study, a baseline with minimal variation is the best way to assure detection of differences.

4.3.6.2 Conditions of Measurement

The ambient light present when pupillary measures are made clearly influences the values obtained. For example, Fosnaugh et al.² determined the effects of ambient light on pupil size and measures of the light reflex. As ambient light varied between less than 0.1 to 200 ft cd, pupil size decreased from 6.5 to 2.5 mm; constriction and dilation velocities decreased from 6.0 to 1.5 mm/sc and from 2.5 to 1.5 mm/s, respectively. The ranges in the Fosnaugh et al.² experiment are similar to those reported elsewhere.^{11,40} In the high ambient light conditions pupil diameter and constriction and dilation velocities increased when an opaque patch was placed over the contralateral eye.² These findings indicate that the design of pupillometers should incorporate features to assure that the ambient light is constant and that the subject consistently opens (or closes) the contralateral eye as the measures are made. In pupillometers where the subject is required to focus or gaze at a near object, accommodation-induced miosis will change pupil size and may diminish the sensitivity of the pupil to a light flash.

4.3.6.3 Effect of Fatigue, Disease, and Legal Drugs

Fatigue tends to decrease pupil size and diminish the response to light through diminished inhibition of the Edinger Westphal nucleus.⁶ Subjects with diabetes mellitus have smaller pupils and a sluggish light reflex.⁴¹ Schizophrenia and other psychiatric diagnoses are associated with sluggish pupillary response to a light flash and other pupillary abnormalities.⁴² The light reflex is obtunded in anxious subjects.⁹

The ingestion of many widely used drugs changes pupillary diameter and the responsiveness to light.^{26,30,43} For example, the following drug classes increase pupil size: anticholinergics (e.g., atropine, scopolamine), sympathomimetics (e.g., epinephrine, ephedrine), and antihistamines

(diphenhydramine). Other drug classes decrease pupil diameter: cholinomimetics (physostigmine, pilocarpine), sympatholytics (e.g., reserpine, guanethidine, alpha-methyldopa), and chlorpromazine. The wide range of drugs that affect pupillary measures represents a challenge to the application of pupillometry in the detection of illegal drugs.

4.3.7 Conclusions

The proposal that pupillary measures could be used to distinguish classes of drugs likely to impair automobile driving performance²⁹ stimulated interest in the use of pupillometry for drug detection applications. More recently pupillometry has been applied to other fitness-for-duty applications on the assumption that small changes in static and dynamic indices of pupillary functions predict CNS impairment. The impairment may be induced by fatigue, disease, or stress. The literature reviewed and the results of the controlled, clinical studies presented in this chapter indicate that several classes of commonly abused drugs have specific, dose-related effects of pupil size and measures of the light reflex. The application of pupillometry for the detection of drugs of abuse is theoretically possible, but the practical utility is limited. Because of the large between-subject variation in pupillary measures, one must know baseline values and ordinary variations for the tested subject. This limits the use of the technique to workplace, military, or institutional applications. The profound influence of ambient light on pupillary measures dictates that the conditions under which measures are made be carefully controlled. Other drugs, fatigue, and some diseases also influence measures of the light reflex and may increase the number of false positive readings. Finally, the magnitude of the effects of the drugs studied are small and transient and often do not exceed the within-subject variability. These considerations challenge the use of pupillometry as a drug detection application.

Acknowledgments

Mr. Ed Hotchkiss (PMI) provided the pupillometer used in the Archway study and collaborated in analyzing results. We are grateful for the help of Ed Bunker and Reginald Fant for their efforts in the previous edition of this chapter and to the students who contributed to these studies: Heide York, Michelle Fank, and Sharifeh Farasat. This research was supported in part, by the NIH Intramural Research Program, NIDA.

4.4.1 Overview of the Problem

The abuse* of marketed medications has been at the forefront of public awareness in recent years, mostly due to widespread reports concerning OxyContin and hydrocodone.¹ While these are highly regulated, prescription-only medications with recognized potential for abuse, even some over-the-counter (OTC) medications have become problematic, either because of their own effects (e.g., ephedrine) or because they are used in the manufacture of other abused substances (e.g., pseudoephedrine, used to make methamphetamine).^{2,3}

The increase in concern seems to reflect a true increase in incidence. The numbers of new nonmedical users of the four major classes of prescription-type drugs (narcotic pain relievers, tranquilizers, stimulants, and sedatives) increased between 1991 and 2001.⁴ There were substantially more new users for narcotic pain relievers than for the other three drug categories — an increase from 628,000 initiates in 1990 to 2.4 million in 2001.⁵ This increase in new users was accompanied by a 76% increase between 1997 and 2000 in the number of primary treatment admissions for narcotic-analgesic abuse.⁶ Initiation of nonmedical tranquilizer use also increased steadily during the 1990s, from 373,000 initiates in 1990 to 1.1 million in 2001.⁵

With reports of increasing abuse has come increasing tension between the need to prevent diversion (illicit use of marketed medication) and the need to keep effective medications available. This tension has been most visible in the realm of opioid analgesics. The need for adequate treatment of pain (e.g., References 7 through 9) coexists uneasily with some state and federal regulatory policies, and with prosecutions of physicians by the Drug Enforcement Agency (DEA) for reported overprescribing; these efforts at control may deter *appropriate* prescribing.^{10–12} A similar effect has been suggested with regard to state-legislated triplicate-prescription requirements and the appropriate prescription of benzodiazepines for agitation and anxiety.¹³ Scheduled analgesics are also understocked at some pharmacies, especially in nonwhite neighborhoods.¹⁴ Underavailability or underprescription of effective medication, resulting in inadequate treatment, may itself be a type of misuse of medication. For the sake of optimal patient care, an appropriate balance must be struck between the opposing needs for availability and control.

* Throughout this chapter, the term *abuse* is used in its broadest sense, referring to any nonmedical or not-as-prescribed use.

It is appropriate to recognize that some medications are more susceptible to abuse than others. If two medications are equally effective for a given indication, the one with lower abuse liability* would obviously be preferred. Information on abuse liability is necessary for the appropriate regulation of medications and provides a basis for education of physicians, patients, and the public. In this chapter we describe the control of marketed medications, abuse-liability assessment procedures for premarketing testing in laboratory animals and humans, considerations of the formulation properties, and postmarketing surveillance of abuse. Finally, we provide three “case studies” of marketed medications that have been abused.

4.4.2 Control of Marketed Medications

In the U.S., substances can be “scheduled” (controlled) under federal law if they are found to have the potential for abuse. Medications being proposed for approval by the U.S. Food and Drug Administration (FDA) may be required to undergo abuse-liability testing and scheduling review. Compounds deemed to have some liability for abuse can be scheduled at one of five levels reflecting how stringently their manufacture and distribution will be regulated. Compounds with high abuse liability and no medically recognized use in the U.S. are placed in Schedule I. (Some Schedule I compounds are used medically in other countries; for example, heroin is approved for analgesia in England.¹⁵) Compounds whose medical utility is recognized are placed in one of the other four schedules (II to V), with higher numbers reflecting less stringent control.

Scheduling serves as a warning to physicians and patients that a particular medication has the potential to be abused. However, the primary purpose of scheduling is to deter diversion and to provide a mechanism for detection if diversion should occur. To that end, requirements for many aspects of the manufacture and distribution of controlled substances are defined in the Controlled Substances Act.¹⁶ The drugs in each schedule are listed, along with the requirements for labeling and packaging, security, storage, record maintenance, manufacturing quotas, and registration requirements both for persons who manufacture, distribute, dispense, import, or export the substances and for places where the substances are manufactured, distributed, dispensed, imported, or exported. Also regulated are the issuance of prescriptions by physicians, dispensing by pharmacists, and prescription labeling, filing, and refilling. For example, prescriptions for drugs in Schedule II cannot be refilled; prescriptions for drugs in Schedules III and IV cannot be refilled more than five times.

Eight criteria for a drug’s scheduling, or exemption from scheduling, are outlined in Section 811 of the Controlled Substances Act:¹⁷ (1) its actual or relative potential for abuse; (2) scientific evidence of its pharmacological effect, if known; (3) the state of current scientific knowledge regarding the substance; (4) its history and current pattern of abuse; (5) the scope, duration, and significance of abuse; (6) what, if any, risk there is to the public health; (7) its psychological or physiological dependence liability; (8) whether the substance is an immediate precursor of a substance already controlled.

Several of these factors (such as 1, 2, 3, and 7) are amenable to premarketing abuse-liability testing. Most abuse-liability testing is targeted to assess the pharmacological entity without regard to its formulation. The past decade has demonstrated that new formulations of old medications add a potentially dangerous twist to assessment of abuse liability.

4.4.3 Premarketing Abuse-Liability Testing

4.4.3.1 Assessment of Pharmacological Entity

Standardized experimental procedures have been developed to evaluate pharmacological entities according to actual or relative potential for abuse, pharmacological effects, and psychological or

* The term *abuse liability*, although standard in behavioral pharmacology, may have unintended implications to clinicians, for whom the word *liability* can connote a threat of litigation. In some contexts, *abuse potential* may be preferable.

physiological dependence liability. One indicator of abuse potential is the extent to which a drug produces reinforcing effects. This is typically estimated in self-administration studies by use of operant-conditioning paradigms that measure the ability of the drug to act as a reinforcer in laboratory animals or sometimes humans. Methods for measuring discriminative-stimulus and subjective effects have been developed to estimate the extent of similarity of the pharmacologic profile of novel compounds to prototypic compounds of a drug class that are already scheduled. In drug-discrimination studies, laboratory animals or human subjects are trained to discriminate the presence or absence of a prototypic drug, and novel drugs are tested for their ability to substitute for the prototypic drug. Subjective-effects studies are conducted with human participants. A novel drug is administered over a range of doses, and its subjective effects are measured on a battery of questionnaires and compared to those of prototypic drugs of abuse. In physical-dependence studies, the test drug is administered repeatedly and then withdrawn; physiological, behavioral, and, in the case of humans, subjective effects are measured. The capacity to produce physical dependence not only can increase the likelihood of abuse but also can increase the adverse consequences of abuse, although physical dependence alone is neither necessary nor sufficient for abuse potential.

The toxicity of abused substances is considered because misuse has the potential to create public-health problems and because the presence or absence of toxic effects can limit abuse liability. Toxicity data can be obtained in studies designed specifically for that purpose as well as from studies of other pharmacological effects such as those listed above.

Self-Administration

The self-administration paradigm is a model of drug abuse widely used to assess the reinforcing efficacy of drugs. In this model, research subjects, usually laboratory animals, are given access to a drug under controlled experimental conditions, and their drug-taking behavior is evaluated. A drug is considered to be reinforcing if the frequency of a designated behavioral response (e.g., a lever press) is increased when drug delivery is contingent on the performance of that response in comparison to the frequency of responses in the absence of the drug. The capacity of a drug to reinforce behavior and, thus, maintain self-administration under experimental conditions is associated with a significant likelihood of abuse by human drug abusers. Since the early 1960s, hundreds of drugs have been tested in operant self-administration paradigms. Drug self-administration has been demonstrated by various routes of administration (intravenous, oral, intragastric, intracranial, intracerebroventricular, intramuscular, and inhalation) and in a wide variety of species (pigeons, mice, rats, cats, dogs, non-human primates, and humans) (for review see Reference 18). The self-administration paradigm is complex; only a brief summary of methods is outlined below. For a more detailed discussion, interested readers are referred to one of the numerous reviews on this topic.^{18–20}

To establish a drug's relative reinforcing efficacy in a self-administration paradigm, a number of procedures can be used: response-rate analysis, concurrent or second-order schedules, progressive-ratio (PR) schedules, and discrete-trial choice.²⁰ The most widely used method, response-rate analysis, employs an operant schedule of reinforcement that defines the work requirement for, or the temporal availability of, the drug, such as a fixed-ratio schedule (FR schedule; a given number of responses is required to obtain the reinforcer) or a fixed-interval schedule (FI schedule; the reinforcer is contingent on the first response emitted after a fixed time interval). Dependent measures typically include the rate of responding (responses/time), temporal response pattern, and the number of drug administrations per session. Duration of access to the drug is an important variable that can be manipulated. Access is typically confined to a limited and predetermined time period (e.g., a 3-h session) in which multiple small unit doses may be obtained. Using fixed access periods, FR and FI schedules generate reliable and reproducible patterns of responding for most drugs.

Self-administration studies can be initiated in one of two ways: direct self-administration or substitution. In the direct self-administration procedure, inexperienced subjects are given access to a test drug, and the extent to which self-administration is initiated and maintained is measured and

can be compared to the rate of behavior observed when placebo and/or other drugs are available. In the more commonly used substitution procedure, self-administration of a standard or prototypic abused drug is established first; the test drug is then substituted for the standard drug, and changes in self-administration behavior are measured.

While self-administration has proved very useful in abuse-liability assessment, several issues must be considered when interpreting the results. One is the reliance on response rate as an index of reinforcing efficacy or reinforcement strength.²¹ Drugs produce a constellation of effects, only a portion of which may be directly related to their reinforcing efficacy. Drug self-administered at the beginning of an experimental session can alter the subject's ability to make the required responses for self-administration later in the session. Thus, nonspecific behavioral effects must be ruled out. One control for nonspecific effects is to incorporate another operant task (such as responding for food) within the experimental session. Another approach is to use more complex schedules of reinforcement (such as second-order and concurrent schedules) (see Reference 20). Another complexity stems from the nonlinear relationship between dose and response rate or drug delivery. The dose–response function generated from self-administration studies is typically shaped as an inverted U. The relationship between dose and response rate or drug delivery is positive at low doses (thus forming the ascending limb of the dose–response curve) and negative at high doses (thus forming the descending limb). In some cases where there is an inverse relationship between unit dose (i.e., dose per injection) and the number of drug deliveries, the total intake of drug can actually be constant across the descending limb of the dose-response curve.^{22,23} Consequently, response rate *per se* may not be a valid index of relative reinforcing strength or efficacy.

Alternatives to response-rate analysis include the progressive-ratio (PR) paradigm and the choice procedure. In the progressive-ratio paradigm, subjects are initially trained to complete a low requirement (e.g., FR-1) for the delivery of a given dose of drug, and then the response requirement is systematically increased until the subject fails to complete it. The last response requirement completed before cessation of responding is known as the “breakpoint”; this serves as the primary measure of the relative strength of the reinforcer. In general, there is an orderly relationship between PR breakpoint and drug dose. In the choice procedure, subjects are trained to respond on at least two separate manipulanda, each associated with its own distinctive conditioned stimulus (e.g., different colored lights). The subject is initially trained on a simple task in which a choice is made between two discriminable drug stimuli such as saline vs. a dose of cocaine. During subsequent testing, the subject is first given an opportunity to sample each choice, and then is required to make a preference choice between the two available manipulanda. In this task, the measure of reinforcing efficacy is the number of drug choices made in a given session and may be expressed as the total percentage of choices for a given drug.

Despite the numerous complexities of self-administration procedures, the data generated from these studies are invaluable for predicting the abuse liability of drugs. When self-administration studies are conducted with the appropriate experimental controls, orderly relationships can be obtained both across and within drug classes. For example, for drugs within the same class, those with higher abuse liability engender more self-administration behavior in the laboratory than related drugs with lower abuse liability. Based on the vast published self-administration literature and epidemiologic reports of drug abuse, self-administration behavior is considered a reliable and strong predictor of the abuse liability of drugs in humans.^{18,24,25}

Self-administration is predominantly used in the animal laboratory, although our review of the literature suggests that an increasing number of self-administration studies are being conducted with human volunteers. As more of the parameters are worked out, it is likely that human self-administration studies will gain even wider use in abuse-liability assessment.

Drug Discrimination

Drug discrimination is an experimental paradigm used to classify drugs based on their interoceptive stimulus effects (i.e., effects occurring within the subject) using a behavioral criterion.²⁶

The drug-discrimination paradigm and the types of data it generates have been reviewed in detail.^{27–30} The paradigm has been used extensively to study pharmacology and to assess abuse liability in humans and nonhumans.^{31–34} In drug-discrimination studies, differential reinforcement is used to establish discriminative control by two or more drugs: subjects are trained to emit one response in the presence of a training drug and to emit an alternate response in the absence of the training drug, while other environmental conditions are held constant. For example, in one training session, a drug dose is administered and responses on only one of two (or more) levers produce reinforcer delivery. In another training session, vehicle or no drug is administered, and responses on an alternate lever produce reinforcer delivery. Repeated reinforcement of correct identifications generally leads to stable discrimination.

After the discrimination is acquired, generalization or substitution testing with novel drug stimuli can be conducted. Doses of a test drug are administered in place of the training drug, and the distribution of responses on the drug-appropriate or vehicle-appropriate lever is recorded. If the novel drug produces predominantly drug-appropriate responses (usually 80% or greater), the novel drug is said to substitute completely and, thus, produce stimuli like those of the training drug. If the novel drug produces responses predominantly on the vehicle or no drug-appropriate lever, the novel drug is characterized as not substituting for the training drug. Intermediate degrees of responding are characterized as partial substitution. Drugs within the same pharmacological class that share interoceptive effects can be differentiated from drugs in other pharmacological classes; even within drug classes, discrimination procedures can differentiate among drugs having activity at different receptor subtypes.²⁷

While drug discrimination has been predominantly used in animal studies, it is also used with humans.³⁵ The procedures used to study drug discrimination in humans are quite similar to those used in laboratory animals, but adapted to the unique capabilities of humans. In the discrimination-training phase, training drugs are paired with letter codes as identifying labels. Drugs are given under double-blind conditions and are not identifiable by appearance or volume, and money typically serves as the reinforcer for correct responses. Most human studies include the concurrent collection of questionnaire data on subjective effects, which has been invaluable in evaluating the interrelationship of behavioral discrimination and subjective effects.

Drug discrimination is not a direct measure of reinforcing efficacy. Although virtually all abused drugs can be trained as discriminative stimuli, most psychoactive drugs, including those that are not self-administered, are discriminable from vehicle or no drug.³⁵ Thus, discriminability in and of itself is not evidence of abuse liability; rather abuse liability may be inferred from the relative similarity of a drug's stimulus effects to those of a known standard or prototypical abused drug. However, there is substantial concordance between discriminative stimulus effects and subjective effects in humans^{35,36} and self-administration behavior in laboratory animals.²⁷

An important caveat in interpreting drug-discrimination data is that results must be considered in the context of the training drug. For example, in subjects trained to discriminate cocaine from saline, D-amphetamine fully substitutes for cocaine while pentobarbital and morphine do not, even though all four drugs have significant abuse potential.^{37,38} Training dose is critical; with higher training doses, generalization dose–response curves tend to be shifted to the right so that higher doses of test drug are needed to produce full substitution. A drug with partial-agonist properties may substitute for a low training dose but fail to substitute for a higher training dose of a full agonist.²⁷ Lower training doses generally produce less pharmacologic specificity than higher training doses, increasing the likelihood of generalization between pharmacologically dissimilar drugs.³⁰

Subjective Effects

Subjective-effect measures have been recognized as a critical element in abuse-liability assessment in humans for several decades.^{39,40} Subjective effects are feelings, perceptions, and moods personally experienced by an individual. Drugs of abuse produce characteristic subjective effects

or interoceptive stimuli that are perceived as positive and desirable to some individuals; drugs that produce these positive mood effects are often described as euphorians.⁴⁰ Because subjective effects are not accessible to observers for public validation, they can only be obtained through self-reports from the individual experiencing them. Subjective-effect measures in the form of questionnaires have been developed to determine whether a drug produces perceptible effects and to determine the quantitative and qualitative characteristics the drug user experiences. They may be used to collect individual self-reports that are consistent across individuals, studies, and situations, can be combined across subjects, can provide reliable and replicable data, and are meaningful to outside observers. Such questionnaires are scientifically useful for assessing a drug's pharmacologic properties, including time course and potency, and can be used to measure the degree of similarity between a test drug and a known standard for abuse-liability assessment. In general, the critical element is the assessment of whether participants like the effects of the drug. Abuse-liability studies, however, usually incorporate multiple questionnaires in order to gather a comprehensive profile of a drug's subjective effects.

The most commonly used questionnaires are scales of global drug effects, subscales of the Addiction Research Center Inventory (ARCI), Profile of Mood States (POMS), Adjective Rating Scales, and the Drug-Class Questionnaire. On measures of global drug effects, participants are asked to integrate the different aspects of a drug's effects and to rate the "overall strength" of those effects, the participants' "liking" of the drug, and the degree to which the drug produces any "good" effects or "bad" effects. The ARCI is a 550-item true/false questionnaire that was developed empirically to assess a range of physical, emotive, and subjective effects of drugs from several pharmacological classes.^{41,42} The ARCI can be tailored to study a particular drug by including only those subscales that are appropriate. The most frequently used scales in abuse-liability studies of acute drug effects are the Morphine-Benzedrine Group (MBG; an index of euphoria), the Pentobarbital-Chlorpromazine-Alcohol Group (PCAG; an index of apathetic sedation), and the Lysergic Acid Diethylamide Group (LSD; an index of dysphoria or somatic discomfort). Increases in the MBG scale, or euphoria scale as it is sometimes called, are associated with significant abuse potential. The Profile of Mood States (POMS) questionnaire is a 65- or 72-item standardized adjective rating scale developed to measure changes in mood in psychiatric populations.⁴³ The POMS does not contain drug-liking or euphoria scales; its utility in abuse-liability assessment derives from determinations of similarity to a standard drug of abuse and from identification of possible aversive effects.⁴⁴ Adjective rating scales are questionnaires on which participants rate symptoms describing global drug effects (e.g., high, strength of drug effect), mood effects (e.g., anxious, depressed), and physical symptoms (e.g., itchy, nausea). In the Drug-Class Questionnaire, participants are asked to indicate which among a list of drugs/drug classes was most similar to the test drug. Experienced abusers can reliably distinguish placebo from active drug and can reliably distinguish among the major drug classes when tested with adequate doses.⁴⁵

Subjective-effect studies require consideration of several experimental factors and control procedures. Participants must be able to comprehend and respond appropriately to questionnaires. Drugs should be administered under double-blind conditions to avoid the introduction of bias into participants' reports. The participants' prior drug exposure could influence responding; most studies assessing abuse potential have used participants with histories of illicit drug use, though a number of studies have been conducted in healthy volunteers without histories of drug abuse.^{40,44–47}

Subjective measures can be used to qualitatively characterize the effects of the drug, and these tend to be consistent across drug classes. Each of the major pharmacological classes has been characterized using the questionnaires described above. Drugs of different pharmacological classes generally produce profiles of subjective effects that are unique to that class of drugs and that are recognizable to individuals. This can be of value to the extent that pharmacological class predicts abuse liability. It can also be useful when testing novel drug classes, for example, when testing drugs that act at newly identified receptors and for which no prototypic drugs are known.

As one might expect, global subjective-effect measures such as “liking” and “disliking” tend not to differentiate between different pharmacological classes of drugs, although they do provide quantitative information regarding the overall magnitude of drug effects. Actually, “liking” has especially good concordance with rates of abuse (i.e., highly abused drugs produce dose-related increases in ratings of liking while nonabused drugs do not⁴⁰) and is therefore probably the single most important subjective-effect measure in human abuse-liability assessment.

Physical-Dependence Capacity

Repeated administration of some drugs can result in tolerance and physical dependence. With the development of tolerance, the effect of a drug decreases if the dose is held constant. Tolerance to the desired effect often leads to escalation of the doses self-administered by abusers. Use of higher doses in turn increases the risk of adverse effects, such as physiological toxicity, psychomotor impairment, and physical dependence. Physical dependence becomes evident when reduction or termination of drug administration is followed by withdrawal signs and symptoms, which can manifest as physiological, psychological, and/or behavioral changes. The biological mechanisms of tolerance and physical dependence have been reviewed elsewhere (see, for example, References 48 and 49).

Physical dependence is no longer considered necessary or sufficient for abuse potential.^{45,50} Nonetheless, physical dependence can contribute to the perpetuation of drug use (as dependent individuals seek drugs to avoid unpleasant withdrawal) and to the cost to the public health, in terms of both human suffering and the expense of medical treatment associated with withdrawal. Physical dependence, and the consequent abstinence syndrome, is significant for some drug classes such as opiates, barbiturates, and benzodiazepines, but less prominent with other highly abusable drugs including cocaine and the amphetamines. In addition, alleviation of the symptoms associated with physical dependence and withdrawal is not effective as a sole treatment for drug dependence.⁵⁰

Physical-dependence capacity can be determined by direct addiction, substitution, or suppression studies. In direct-addiction studies, a test drug is administered repeatedly over time; doses are initially low and then gradually increased as tolerance develops to toxic effects. After subjects have been stabilized at a specified dose, tolerance and other effects of chronic drug administration are evaluated; methods for evaluating tolerance have been described in detail elsewhere.^{20,51} Physical dependence can then be documented by abrupt discontinuation of drug administration or by administration of a selective antagonist for the appropriate receptor type (e.g., naloxone during chronic administration of an opioid). Subjects are observed for signs of an abstinence syndrome. With human subjects, self-report measures can also be included to gain qualitative information about the characteristics of the abstinence syndrome, including dysphoric effects. Drug-seeking behavior can also be monitored, either by recording requests for test drug or other medication during the withdrawal period (for example, see Reference 52), or by giving subjects the opportunity to self-administer drug.^{53,54}

The substitution and suppression procedures, variations on direct addiction, have also been used to evaluate physical-dependence capacity. These procedures have chiefly been used with the opioids^{45,52} and are described only briefly here. In suppression studies, subjects are initially made physically dependent on a prototypical opioid agonist, for example, morphine administered in four injections/day. In test sessions, agonist administration is abruptly withdrawn, and at the peak of withdrawal (e.g., approximately 30 h after the last morphine dose) test medications are administered and evaluated for their ability to suppress withdrawal. The ability of opioid agonists to suppress the abstinence syndrome was documented using this methodology. In substitution studies, the maintenance drug is replaced with doses of test drug or placebo. The ability of the test drug to prevent the onset of the withdrawal syndrome is assessed over a specified period of time (for example, 24 h). This procedure enables crossover studies with multiple drugs or multiple dose

levels of a test drug; subjects are restabilized on the maintenance medication between experimental test sessions.

4.4.3.2 Assessment of Preparation

Pharmacokinetics

The abuse liability of a drug is influenced by its pharmacokinetic properties and the numerous factors that determine its distribution, metabolism, and excretion. One important factor is the speed with which a drug is delivered to the central nervous system. In general, abuse potential is enhanced by speeding the delivery of drug to the brain, and this closely corresponds with the rate of rising drug concentration in arterial blood (see also Reference 55). Increased speed of delivery shortens the interval between drug administration and the perceived onset of the drug's pharmacodynamic effects, a behavioral feature considered critical to abuse potential.⁵⁶ Routes of drug administration that provide a more rapid delivery are associated with greater abuse liability. Because route of administration largely determines the speed of delivery, one of the simplest means of modifying the speed of drug delivery is to change the route of administration. For most drugs the rank order for routes of administration from fastest to slowest delivery are typically as follows: inhalation (e.g., smoking) > intravenous > intramuscular \approx subcutaneous > intranasal > oral. Cocaine is an example of a drug with abuse potential that increases across routes of administration, with oral having the lowest dependence potential and intravenous and smoked having the highest.^{57–62} The relationship between speed of onset and abuse potential has also been shown for pentobarbital and diazepam.^{63,64} There are some exceptions to these rules; these include drugs that are themselves inactive but produce active metabolites (i.e., prodrugs) and drugs with particularly poor bioavailability when administered by a specific route.

Capacity to Be Made into More Abusable Preparation

Because faster onset of action is associated with higher potential for abuse, abuse-liability assessment should include consideration of whether a formulation can be altered to increase the speed of onset. There are numerous examples of abuse of a medication by a route other than that intended by the manufacturer. The sustained-release oral form of oxycodone, designed to deliver an initial rapid dose followed by slow release, has been widely abused by chewing the tablet, thus releasing the entire content of the tablet at once.⁶⁵ There is also evidence for intravenous use of sublingual buprenorphine tablets.⁶⁶ Transdermal systems developed to deliver medication slowly for extended periods of time have been prime targets for misuse,⁶⁷ as discussed below in the case study of fentanyl.

A wide range of possible uses and misuses must be considered in both the development of formulations and in regulatory decisions. Formulations need to be tested as they might be used, not just as they are meant to be used. While it is possible to develop formulations that lower the abuse potential of a pharmacological constituent, every effort must be made to challenge the formulation to substantiate such a claim.

Availability

The availability of a marketed medication is a key determinant of its abuse liability. A highly abusable medication may have a low rate of abuse if it can only be obtained, for example, in hospital settings. Even within hospital settings, the degree to which availability and, thus, opportunity play a role in incidence of abuse is illustrated by the greater incidence of substance abuse among anesthesiologists than among other physician groups.^{68,69} Increasing the availability of a medication with a low rate of abuse can substantially increase the incidence of abuse. Two examples of this

phenomenon are described below in the case studies: abuse of both fentanyl (an agonist opioid with high abuse liability) and butorphanol (an agonist-antagonist opioid with moderate abuse liability) increased when each drug was approved for prescribed use in outpatients, despite the use of formulations that might have been expected to minimize abuse liability.

Even drugs with low potential for abuse can have periodic increases in abuse if they are widely available, as discussed below in the case study of the OTC cough suppressant dextromethorphan. Other examples include anticholinergics^{70,71} and antihistamines.⁷² Abuse of these drugs tends to be mostly limited to particular populations — patient populations in the case of anticholinergics, and youth in the case of dextromethorphan. That the abuse liability of a drug may differ across populations, and that different populations may abuse a drug for different reasons, is a possibility that needs consideration when selecting participants and outcome measures for abuse-liability studies. Abuse-liability testing has come to focus on assessment of euphoriant effects in experienced drug abusers rather than patterns of use in the clinical populations for whom the drug is intended or in other populations,⁷³ and while this approach is probably appropriate in most cases,⁷⁴ it does not always suffice (as illustrated below in the case studies).

In summarizing the relationship between availability and abuse, we need to recognize that there is no formula to predict exactly how much abuse will occur, and that the relationship may wax and wane over time, as discussed below in the case studies. Still, there are a few “rules of thumb.” Given equal availability, drugs that produce more positive mood effects are more likely to be abused than those with less positive effects. However, all psychoactive drugs, even those with minimal positive mood effects, have the potential for abuse, even if only for their mood-altering effects. Increasing the availability of a drug will likely increase the absolute numbers of abuse incidents. Finally, acute toxicity has the opposing effects of decreasing the likelihood of abuse while increasing the adverse consequences if abuse should occur.

4.4.4 Postmarketing Surveillance

Postmarketing surveillance is a continuation of the risk assessment conducted during drug development.^{75–78} Postmarketing surveillance is necessary because the number of patients exposed to a new drug during premarket testing is usually too small to detect low-incidence adverse events and determine statistically whether those events are caused by the new drug. In addition, patients selected to participate in clinical trials often have more limited ranges of medical conditions and concomitant medications than those who are prescribed the medication after marketing. In the U.S., the FDA maintains the MedWatch program to collect adverse-event reports on marketed medications and to provide safety information for health-care professionals and the public.⁷⁹ Pharmaceutical companies often establish their own monitoring programs for adverse events.

Surveillance systems also exist for drug abuse (for review, see Reference 80). Through the Substance Abuse and Mental Health Services Administration (SAMHSA), of the Department of Health and Human Services, the U.S. federal government maintains the Drug Abuse Warning Network (DAWN),⁸¹ which monitors trends in drug-related emergency-department visits and deaths (although the quality of its data has been questioned⁸²). SAMHSA also conducts several surveys on drug use and treatment.⁸³ One SAMHSA survey, the National Survey on Drug Use & Health, formerly called the National Household Survey of Drug Abuse (NHSDA/NSDUH), is administered annually to a statistically representative sample to collect data on the use of illicit drugs, the nonmedical use of licit drugs, and the use of alcohol and tobacco products. Another SAMHSA survey, the Drug and Alcohol Services Information System (DASIS), collects data on treatment facilities for substance abuse, including services offered, numbers of individuals treated, and the characteristics of individuals admitted to treatment. Two of the data sets within DASIS are the Treatment Episode Data Set (TEDS) and the National Survey of Substance Abuse Treatment Services (N-SSATS, formerly known as UFDS). TEDS has demographic and drug-history information about individuals admitted to treatment, primarily by providers receiving public funding.

N-SSATS is an annual census of U.S. treatment facilities registered with SAMHSA and contains information on their location, organization, structure, services, and utilization.

While these surveys are very informative about national trends in drug use, they probably have limited utility as early-warning systems for abuse of newly marketed medications. Ideally, detection of an emerging abuse problem would occur before the numbers of affected individuals grew large enough to be measurable on national surveys. More directed postmarketing surveillance has been used to monitor for diversion and abuse for two recently marketed medications, tramadol and sibutramine.⁸⁰ The tramadol surveillance program included spontaneous reports to the manufacturer and adverse-event data from MedWatch, but also used a key-informant network of treatment researchers who completed quarterly questionnaires. Proactive surveillance via the informant network increased the detection of cases of physical dependence, diversion, and abuse compared to the spontaneous-reporting systems.^{84–86} In the sibutramine surveillance program, an anonymous questionnaire was completed by individuals in community- and university-based treatment programs every 6 months for 3 years.^{80,87} The questionnaire requested information on experiences with sibutramine, phentermine (a scheduled anorectic agent), and a drug with a fabricated name. Early detection of clinically important diversion or abuse of a marketed medication through postmarketing surveillance could enable reconsideration of scheduling decisions before serious problems develop.

4.4.5 Case Studies

In practice, the regulatory status of a marketed drug rarely emerges in a tidy way from experimentally obtained abuse-liability data. In this section, we examine the histories of three drugs (butorphanol, fentanyl, and dextromethorphan) chosen because the prediction of abuse liability for each drug has been imperfect for different reasons. For each drug, we reviewed three types of information: abuse-liability studies in laboratory animals and humans; case reports and news items concerning diversion, abuse, addiction, or overdose; and news items and official documents concerning changes in regulatory or commercial status. Sources included papers found through the Medline and PsycInfo databases (1966 through 2003) supplemented with references cited in the papers themselves; items from the popular press found through the Lexis/Nexis database (early 1970s through 2003); and the Web sites of the FDA and the DEA.

For each drug, the prevalence of abuse was partly attributable to its absolute availability — for example, the over-the-counter status of dextromethorphan (DXM) or the expansion of fentanyl and butorphanol from inpatient to outpatient use. But the pattern of abuse for each drug was distinctive and probably could not have been predicted from the available experimental abuse-liability data.

4.4.5.1 Butorphanol

Table 4.4.1 shows a selective timeline of the evaluation, abuse, and regulation of butorphanol, an opioid with mixed activity at mu and kappa receptors. The most salient aspects of the drug's recent history can be summed up in terms of two questions:

Who abused it? Most of the reports have concerned patients experiencing iatrogenic physical dependence, especially after 1991, when the drug was approved for outpatient use in a nasal-spray formulation. Reports seemed especially to increase when the drug was marketed for a new indication, migraine — a disorder with recurrent symptoms and the possibility of rapid rebound of symptoms if medication is overused.⁸⁸ Anecdotally, the modal pattern of abuse seemed to be escalation of use in patients with legitimate prescriptions,⁸⁹ even though some patients reported that the acute effects of the drug were extremely unpleasant.⁹⁰ There have been very few reports of diversion or abuse by nonpatients, and essentially no reports of use for euphoriant properties or for the avoidance of withdrawal from other opiates such as heroin.

Why was this pattern not predicted? Published abuse-liability studies with butorphanol have generally been conducted in experienced abusers of mu-agonist opioids, and have generally focused

Table 4.4.1 Butorphanol Timeline

Year	Animal Data	Human Lab Data/Clinical Trials	Case Reports/Case Series/Surveys	News Items	Regulatory/Commercial Developments
1975		s.c.: Doses up to 8 mg do not precipitate morphine withdrawal; doses over 8 mg psychotomimetic ¹¹⁹ s.c.: Lower abuse potential than codeine or propoxyphene; no increase in liking w/doses 4–48 mg/day over a month, unlike pentazocine ^{120–122} i.m.: No drug-seeking noted in participants in Bristol Labs Phase III trials after abrupt termination of drug ⁹¹			
1976–1978					
1978					i.m.: FDA's Drug Abuse Advisory Committee (DAAC) votes 12–2 to schedule butorphanol; recommendation not followed; scheduled in only one state (Oklahoma) ⁸⁹ i.m.: FDA maintains position against scheduling due to absence of evidence of abuse; DAAC votes 9–4 in support of FDA ⁸⁹
1980					
1981	In rats, produces only mild withdrawal syndrome (similar to other partial agonists), but tends to precipitate withdrawal from morphine ¹²³				
1982	Baboons self-administer butorphanol, as well as nalbuphine and pentazocine (finding published 4 years after presentation) ¹²⁴				

Table 4.4.1 Butorphanol Timeline (Continued)

Year	Animal Data	Human Lab Data/Clinical Trials	Case Reports/Case Series/Surveys	News Items	Regulatory/Commercial Developments
1983			i.m.: Case report of diversion from hospital in Michigan ¹²⁵		DAAC votes 10–2 against scheduling of theoretical oral form; FDA considers diversion reports not of great significance ⁸⁹
1984	Physical dependence clearly shown in rats ⁹⁴		i.m.: 5 male teens in Mississippi using i.v. with antihistamine to get high; minor withdrawal syndrome; 1 fatal OD ¹²⁶		
1985			i.m.: Frequent diversion in hospitals; ^{127,128} some patients escalating use ¹²⁹		i.m.: Some hospitals indicate having tightened controls to Schedule II–IV level; some exclude drug from formulary ¹²⁷
1988		i.m.: In 3-choice discrimination in methadone patients: butorphanol more like naloxone than saline or hydromorphone; very little abuse liability ¹³³			
1989	In morphine-maintained rhesus monkeys: butorphanol discriminated as saline, not as naltrexone ¹³²				
ca. late 1980s			Nasal spray: 18 healthy volunteers in Bristol-Myers “first time in humans” study; withdrawal not seen when drug discontinued after 16 days ⁹²		

1990

i.m.: Very little abuse liability in methadone patients¹³³

Nasal spray: Bristol-Myers clinical trial in post-Caesarian-section pain; no assessment of abuse liability or withdrawal⁹³

1991

In rats, naloxone-induced withdrawal is just as severe for butorphanol as for morphine⁹⁵

Nasal spray: Very little abuse liability in male opioid abusers¹³⁴
i.m.: In 2-choice discrimination: butorphanol more like hydromorphone than like saline; withdrawal both morphine-like and kappa-like; but subjects choose sedative, not more butorphanol, for relief; increases liking, but not MBG; sometimes identified as barbiturate¹³⁵

Nasal spray: FDA approves nonscheduled, despite DAAC concerns (e.g., that clinical trials were insensitive to abuse liability)⁸⁹

1992

Nasal spray advertised for use in migraine; no published clinical trials on spray in migraine; Texas increases control amid reports of spray users unable to stop⁸⁹

1993–1994

Nasal spray: Chicago-area neurologist writes that of his 24 migraine patients, 13 had had ADRs; “extremely stoned,” “stuporous”; 6 said it was worst experience of their lives; no withdrawal mentioned⁹⁰

Nasal spray: MedWatch reports increase⁸⁹

Table 4.4.1 Butorphanol Timeline (Continued)

Year	Animal Data	Human Lab Data/Clinical Trials	Case Reports/Case Series/Surveys	News Items	Regulatory/Commercial Developments
1994	In cynomolgus monkeys, butorphanol acts only as an agonist ¹³⁶	i.m.: Male postaddicts; 3-choice discrimination: On VAS scales: increases High, Liking, Good, and Not Bad, but on ARCI, increased PCAG, not MBG; Drug class: ID'd as sedative, not opiate; Conclusion: more kappa than mu effects ¹³⁷ i.v.: Healthy volunteers; on VAS, increases Sedated (also Liking, but not dose-related); on ARCI, increases PCAG and LSD; main difference from effects in opiate abusers: psychomotor impairment ¹³⁸	Nasal spray: Review of headache treatments acknowledges possibility of symptom rebound and dependence with overuse of analgesics, including spray ⁸⁸		
1995				Nasal spray: in August, suicide by gunshot during withdrawal (not widely reported until 1997) ¹³⁹	FDA survey: 39 of 47 states report diversion or abuse; 7 have tried to schedule butorphanol; more than half have special controls at hospitals; most-abused form is nasal spray. FDA leaves regulation to states ⁸⁹ Nasal spray: in April, Bristol-Myers asks FDA to control ¹⁴⁰ Nasal spray: Chicago-area pharmacists are said to dilute it to limit its abuse liability ⁸⁹ Nasal spray: FDA recommends scheduling to DEA, but decides against sending Dear Doctor letter ¹⁴¹ DEA places butorphanol in Schedule IV
1996					
1997		i.v.: In healthy volunteers, butorphanol-induced ratings of "elated" (though not liking) actually increase during cold-water pain ⁹⁶		Nasal spray: Reports of addiction associated with rebound migraine ¹³⁹ <i>Neurology</i> publishes historical review ⁸⁹ coauthored by father of 1995 suicide	

1998

i.m.: Disliked by heroin/opiate abusers^{142,143}
i.m.: Opioid chippers; hydromorphone vs. not hydromorphone discrimination; with these instructions, butorphanol does not substitute for hydromorphone at any dose; VAS: Increases both Good and Bad, not Liking; no effects on ARI¹⁴⁵

Nasal spray: Wrongful-death suits filed¹⁴⁴
Nasal spray: Scattered news reports of addiction continue¹⁴⁶

2001

i.m.: Heroin chippers; butorphanol compared with a selective kappa agonist (enadoline) and a selective mu agonist (hydromorphone) and was more mu-like than kappa-like on most measures¹⁴⁷

Nasal spray: First news report of recreational use: fatal OD in teen girl¹⁴⁸
Nasal spray: FDA gives Mylan abbreviated NDA for generic

2002

i.m.: Methadone-maintained humans; trained on "naloxone vs. placebo vs. novel" discrimination; butorphanol produces 70% naloxone responding, 29% novel responding¹⁴⁹

Nasal spray: Another news report of an addicted provider¹⁵⁰
Nasal spray: FDA approves generic form Roxane

Note:

on whether butorphanol produces liking or euphoria and on whether it has morphine-like properties. The absence of such findings may have contributed to the nonscheduled status of the drug (until it was placed in Schedule IV in 1997). One review article⁹¹ summarizes “data on file” at Bristol Laboratories from 1978 as follows: “During Phase III clinical trials, [injectable] butorphanol was administered chronically at therapeutic doses to patients for as long as 9 months and then abruptly terminated. No withdrawal symptoms or compulsive drug-seeking behavior were precipitated.” The patient population is unspecified; it seems unlikely that it consisted largely of patients with migraine or that they had the opportunity to self-administer the drug more frequently or in larger doses. Similarly, the later clinical trials supporting the nasal-spray formulation^{92,93} did not include patients with migraine and would not have been able to detect a cycle of rebound headache and dose escalation.

Comments. The clearest lesson from the butorphanol experience is that when a drug is introduced to a new population, it is important to determine whether extant abuse-liability studies will generalize to that population. If not, then clinical trials should be designed to detect signs of abuse in that population, and careful postmarketing surveillance should occur. The goal is not to prevent patient access to necessary medications, but to ensure that providers and patients have adequate information about the risks of such medications.

One of the risks of butorphanol, its physical-dependence potential, emerged in animal studies^{94,95} more clearly than in human abuse-liability studies. It is also interesting to note that the human experimental data that seem most consistent with marketing experience did not appear until 1997, when it was shown that the modest euphoriant effects of butorphanol are more prominent in the presence of a painful stimulus (a finding opposite to what has been observed with most morphine-like drugs).⁹⁶ Each of these findings shows, of course, that relevant abuse-liability data are easiest to pick out in hindsight. Still, future marketing and regulatory decisions may benefit from increased attention to the multiplicity of ways in which a drug could be prone to abuse.

4.4.5.2 Fentanyl

Table 4.4.2 shows a selective timeline of the evaluation, abuse, and regulation of fentanyl, a potent agonist at mu-opioid receptors. Again, the most salient aspects of the drug’s recent history can be summed up with two questions:

Who abused it? In contrast to butorphanol, fentanyl has been abused primarily by nonpatients who had access to the drug. There have been numerous reports (far too many to include in the timeline) of diversion and abuse of fentanyl for its euphoriant properties. Until 1990, these reports usually involved health-care providers with access to the intravenous formulation in hospital settings. After 1990, when a transdermal-patch formulation became available to outpatients, abuse spread to a much broader population. Yet only a very small proportion of the reports concerned patients for whom legitimate prescriptions had been written — again in contrast to butorphanol. The modal pattern of abuse was through illegitimate access to patches (taken from trash cans, removed from nursing-home patients, or, in one twice-published case,^{97,98} removed from a dead body), followed by inhalation, ingestion, or injection of their contents.^{99–103}

Why was this pattern not predicted? The highly euphorogenic nature of fentanyl was actually clear in abuse-liability studies as early as 1965,¹⁰⁴ and the drug was accordingly placed in Schedule II of the 1970 Controlled Substances Act; this was the most restrictive possible placement that still permitted medical use. What was apparently not foreseen, when the patch formulation was approved for outpatient use in 1990, was that its slow-release properties would be defeated by individuals seeking intoxication. The published literature appears to contain no abuse-liability studies for the patch formulation.

Comments: The obvious lesson of the fentanyl experience is that abuse-liability studies must take into account the possibility that an intended slow-release system will be subverted by users. How to respond to this possibility is a difficult question. Sometimes it may be possible to develop a formulation that is more difficult to subvert, such as a subcutaneous implant. But it is also

Table 4.4.2 Fentanyl Timeline

Year	Human Lab Data/Clinical Trials	Case Reports/Case Series/Surveys	News Items	Regulatory/Commercial Developments
1965	i.v.: In postaddicts, more euphorogenic than morphine ¹⁰⁴			
early 1970s				i.v.: Sublimaze and Innovar introduced in U.S.; for hospital use only; on Schedule II
mid-1970s		i.v.: Abuse reported among health-care providers ¹⁵¹		
1980s			i.v.: Scattered reports of diversion by health-care providers; ^{152,153} also some reports of illicitly manufactured powder ¹⁵⁴	
1989			Lozenge: Some controversy over appropriateness of "lollipop" ⁹ formulation during multisite trials ¹⁵⁵	
1990				Patch: FDA approves Duragesic; no abuse-liability studies for patch in published literature
1991–1993		Patch: Scattered reports of misuse and ODs ^{103,156}	Illicit fentanyl: Many reports of fatal ODs on powder sold as "Tango & Cash," ¹⁵⁷ referred to as a "serial killer" ^{108,158}	
1992				Illicit fentanyl: Bill introduced in Congress to equate possession penalties with those for heroin possession ¹⁵⁹
1993				Lozenge: FDA approves Oralet for hospital use
1994			Lozenge: More controversy over appropriateness of "lollipop" formulation ^{160–162}	Patch: FDA sends Dear Doctor letter
1995			i.v.: Medical student in New York City dies from self-injected fentanyl ¹⁶³	
1996	i.v.: In healthy volunteers, euphoriant effects blunted during pain ¹⁰⁶			
1997				
1998				Lozenge: FDA DAAC recommends approving Actiq for outpatient use
2000–2003		Patch: another case series on abuse and OD ¹⁶⁴	Patch: More stories on diversion and OD ^{165–167} Lozenge: fatal OD with use of 3 simultaneously ¹⁰⁵	Lozenge: FDA approves Actiq for outpatient use

Note: See Table 4.4.1 for abbreviations.

important that the drug be available in formulations that patients need, such as the fentanyl lozenge approved in 1998 for breakthrough pain in patients with cancer — despite the likelihood that these formulations will be abused. (There has already been a newspaper report implicating fentanyl lozenges in the death of a man who used three lozenges simultaneously.¹⁰⁵) Higher scheduling of fentanyl would make the drug completely unavailable for medical use. The regulatory response to fentanyl abuse at the federal level has been to maintain close FDA monitoring of advertising claims, commercial manufacture of new formulations, and imports through Internet pharmacies. Additional measures, such as tighter prescription tracking, have been considered by individual states such as Florida.

As mentioned above, most reports of fentanyl abuse have not involved iatrogenic addiction in patients. As with butorphanol, the human experimental data most consistent with this did not appear until 1996, when it was shown that the euphoriant effects of fentanyl are blunted in the presence of a painful stimulus.¹⁰⁶ Clearly, however, low incidence of iatrogenic addiction or abuse may not predict the likelihood of abuse in nonpatient populations.

Earlier in the chapter, we pointed out that the relationship between drug availability and abuse may wax and wane over time. In the case of fentanyl, this can be seen in the differing results of two published analyses. In the first analysis, from 1990 to 1996, fentanyl prescriptions increased 1168% while an index of overdose admissions (DAWN mentions of fentanyl, including both licitly and illicitly manufactured fentanyl) actually decreased 59%.¹⁰⁷ But in the second analysis, from 1994 to 2001, both measures increased, with the largest relative increase in DAWN mentions occurring in 1997.¹ This pattern may be partly attributable to negative news coverage of both illicit and diverted fentanyl, which, based on our Lexis/Nexis search, peaked from 1991 through 1993, then declined from 1994 to 1999, perhaps permitting some “forgetting” of the drug’s risks. Negative publicity, or lack thereof, is likely to have complex effects on a drug’s abuse liability; according to one newspaper report, when police used bullhorns to warn of the lethal potency of a batch of illicitly manufactured fentanyl being sold under the name Tango & Cash, local attempts to purchase the drug actually increased.¹⁰⁸

Among the other trends we noticed in press coverage of fentanyl was that, although reports of overdoses from illicitly manufactured fentanyl tended to be lurid (often referring to the drug or its manufacturers as “serial killers”), this line of reportage rarely influenced the tone of stories about pharmaceutically used formulations. Even as reports of street-fentanyl fatalities peaked in the early 1990s, several newspapers ran positive pieces on the therapeutic potential of the fentanyl patch. Although there are several different ways in which this can be viewed, it is probably encouraging that abuse of fentanyl in one form did not automatically lead to the derogation of other forms.

4.4.5.3 Dextromethorphan

Table 4.4.3 shows a selective timeline of the evaluation, abuse, and regulation of DXM, a nonnarcotic cough suppressant with activity at sigma and PCP receptors. Unlike butorphanol and fentanyl, it has never been scheduled in the Controlled Substances Act, and it is available without a prescription in various over-the-counter formulations.

Who abused it? Most reports of abuse have involved teenagers either specifically seeking a dissociative/hallucinogenic experience or simply seeking any intoxicating effect. The pattern of abuse has generally been sporadic since the introduction of DXM in the 1950s, but reports of abuse have been more frequent and widespread since the mid-1990s, coinciding with the more rapid spread of information on the Internet.

Why was this pattern not predicted? As with butorphanol, initial abuse-liability studies were generally conducted in experienced abusers of mu-agonist opioids, and generally focused on whether DXM produced liking or euphoria and on whether it had morphine-like properties.^{109,110} Participants in the first study¹⁰⁹ seemed completely insensitive to the acute dissociative effects of large single oral doses (up to 800 mg), and even when larger doses were used (up to 1800 mg),

Table 4.4.3 Dextromethorphan (DXM) Timeline

Year	Animal Data	Human Lab Data/Clinical Trials	Case Reports/Case Series/Surveys	News Items	Regulatory/Commercial Developments
before 1956					Romilar tablets (DXM-only preparation) not controlled, but require prescription in U.S. ¹⁶⁸
1956					FDA moves Romilar tablets from prescription status to OTC ¹⁶⁸
1962		s.c. and oral: No acute subjective effects in postaddict prisoners; chronic subjective effects all aversive; also, no effects of active metabolite DO ¹⁰⁹			
1964–1969			Sporadic abuse outside U.S. ^{169–171}		
1970					DXM exempted from Controlled Substances Act ¹⁷
1971		s.c. and oral: Acute psychotomimetic effects in postaddict prisoners, but no increase in VAS Liking or ARC MBG; Drug ID: barbiturate or amphetamine; Subjective effects: similar to nalorphine ¹⁰			
ca. 1973					Romilar taken off market after increase in abuse ¹⁷²

Table 4.4.3 Dextromethorphan (DXM) Timeline (Continued)

Year	Animal Data	Human Lab Data/Clinical Trials	Case Reports/Case Series/Surveys	News Items	Regulatory/Commercial Developments
1976					DO removed from Schedule II
1982					WHO concludes no evidence to warrant control ¹⁷³
1986					DXM made prescription-only in Sweden after reports of teen abuse there ¹⁷⁴
1988			First known fatal ODs, in Sweden: one suicide, one possible abuse ¹⁷⁵		
1990			Case of Rofitussin-drinking dependence in U.S. meeting DSM-III-R criteria; patient's initial attempts to seek help are met with disbelief (pharmacist says that getting high on cough syrup is impossible) ¹⁷⁶		Hearings by Pennsylvania drug board, then FDA; Penn. board was asked to put DXM on Penn.'s Schedule V (limiting it to pharmacy or physician dispensing and to patients over 18); FDA reviews reports of abuse from several states; decides to leave control to states ¹⁷⁷
1991	In rats: DO induces PCP-like behavior, but DXM does not ¹⁷⁸				
1992			Two case reports of DXM-associated mania ^{179, 180}	First newspaper mention of recreational use in U.S., in advice column ¹⁸¹	
1993			Case report of mania ¹⁸² Abuse by two teenage boys in southern U.S. ¹⁸³	<i>Harper's</i> piece says abuse of DXM cough syrup is well known among teens but rarely written about ¹⁸⁴	

1994	In rats, DXM itself has PCP-like discriminative-stimulus effects ¹⁸⁵		Another advice-column mention ¹⁸⁶ November: William White's DXM FAQ appears on Web ¹¹⁵		
1995		Case report of massive long-term ingestion of cough syrup ¹⁸⁷	News report that DXM-syrup fad among teens is already declining in popularity; ¹⁸⁸ another advice-column mention ¹⁸⁹		
1996		School survey in rural Pennsylvania: DXM-cough-syrup abuse fairly well known, first heard of in 1987 ¹⁹⁰ Two cases of mania with daily use ¹⁹¹		Drixoral Cough Caps apparently discontinued	
1997–1998	In rats, DXM has sedative effects and DO has PCP-like effects ¹⁹²	Abuse in Korea ^{193,194} Two nonfatal ODs in California ¹⁹⁵	A few more news reports on abuse of cough syrups (e.g. ¹⁹⁶) and sale of DXM by mail order (e.g., ¹⁹⁷)		
1999	In rats and rhesus monkeys, "DXM has some PCP-like effects, but they are produced more reliably by DO" ¹⁹⁸	Retrospective case series of ODs in Switzerland ¹⁹⁹ and Texas; increase shown in Texas ²⁰⁰	Reports on sales of pure DXM over Internet ²⁰¹	DEA official says that upswing in DXM abuse is "out of our realm [of jurisdiction]" ²⁰²	
2000		Oral: in 9 detoxified alcoholics and 10 healthy controls, DXM (2 mg/kg) has ethanol-like effects, with higher scores in controls ²⁰³	More OD reports in news, concerning both OTC formulations and pure DXM; Web sites criticized ^{204–207}	FDA official says that DXM is not approved for use outside marketed formulations ²⁰⁸	
2001			Fatal OD on Coricidin ²⁰⁹ Suspicion that teens are distilling pure DXM from cough syrup ²¹⁰	Local efforts to move DXM preparations behind the counter ²¹¹	

Table 4.4.3 Dextromethorphan (DXM) Timeline (Continued)

Year	Animal Data	Human Lab Data/Clinical Trials	Case Reports/Case Series/Surveys	News Items	Regulatory/Commercial Developments
2002		Oral: in 10 methadone-maintained inpatients, DXM (120, 240, and 480 mg/day for 4 days each to reduce methadone tolerance) induced some drowsiness; no changes in subjective effects or ARI; several patients reported intoxication at the highest dose ²¹²	Poisoning in a youth who tried to extract DXM from cough syrup with "Agent Lemon" procedure ²¹³	More local reports of abuse by teens, e.g., in New Hampshire; ²¹⁴ increase shown in ODs near Chicago ²¹⁵	Failed bill in North Dakota to ban sale of cough medicine to minors; ²¹⁶ more pharmacists move DXM behind the counter ²¹⁷
2003			Case of liver toxicity from abuse of Coricidin, due to acetaminophen ¹¹⁴	More ODs, at least one fatal; ²¹⁸ another acetaminophen poisoning from abuse of an OTC preparation ¹¹³	Bill in Texas to ban sale of cough medicine to minors and outlaw abuse; in committee; ²¹⁹ Palo Alto high-school resource officer on one-man "crusade" to make pharmacy chains change shelf placement of DXM products; ²²⁰ Pharmacist in Iowa City puts DXM products behind the counter ²²¹

Note: See Table 4.4.1 for abbreviations.

no dissociative effects emerged, perhaps because the outcome instruments had not been designed to detect them. The primary effect of single doses was drowsiness. Only chronic dosing produced strong effects, described as “confusion” and “loss of memory”; the participants found these effects frightening. The second study¹¹⁰ found slightly stronger evidence for acute effects, such as increases on the PCAG (sedation) and LSD (dysphoria) scales of the ARCI, but again, no measures were used that would have specifically identified dissociative effects, and the participants did not report liking the drug.

Comments: The clearest lesson from the DXM experience is that when designing an abuse-liability study, it is important to consider all possible effects that can make a drug abusable, bearing in mind that effects to which a particular study sample is insensitive or averse may be desired effects in others.

In the case of DXM, however, the desirability of the intoxicating effects appears to be confined largely to individuals in their teens and twenties — an observation consistent with the finding that the use of hallucinogens peaks at age 19 and then declines rapidly, regardless of birth cohort.¹¹¹ As a result of the drug’s limited appeal, outbreaks of abuse have usually been self-limiting. This may be among the reasons that DXM remains unscheduled by the DEA and retains its over-the-counter status by FDA regulations. Several states have seen legislative efforts to restrict the availability of DXM either fail or become stalled. However, in 2006, legislation passed in Illinois banned the sale of DXM in pure form. Some pharmacists have chosen to keep DXM-containing preparations behind the counter, but this approach has been criticized because it forces recreational users underground rather than giving pharmacists a chance to engage them.¹¹² (In one newspaper report, a pharmacist stated that he had been able to dissuade two teenagers from buying and abusing DXM-containing cough syrup by warning them of its risks.¹¹³ Whether they obtained the drug elsewhere is not known.) The response of manufacturers has been to discontinue sales of DXM-only cough formulations; this may discourage abuse, but may also increase toxicity from other ingredients such as acetaminophen when abuse does occur.¹¹⁴

As mentioned above, outbreaks of DXM abuse seem to have increased with the rise of the Internet. Literature reviews and newspaper articles on DXM have frequently included pejorative or alarmist comments about the abundance and inaccuracy of DXM-related information found on the Internet. Yet the seminal Internet document about DXM, William White’s DXM FAQ (Frequently Asked Questions)¹¹⁵ — first posted to Usenet newsgroups in 1994, and made available on the Web in November of that year — was exhaustive (with scholarly interpretations of hundreds of studies from peer-reviewed journals) and balanced (with the risks of DXM abuse emphasized throughout). If the mid-to-late-1990s upswing in DXM abuse is to be attributed partly to the Internet’s ability to spread information widely, perhaps it should also be attributed to the tendency of some readers not to absorb information thoroughly.

4.4.6 Further Reading

To avoid redundancy with several recently published reviews, we have limited our discussion of techniques for abuse-liability assessment. Interested readers are referred to these reviews,^{73,74,116–118} which appear in a special issue of the journal *Drug and Alcohol Dependence*.

INTRODUCTION

This chapter provides an overview of clinical and forensic-medical aspects of man's favorite recreational drug, alcohol (ethanol or ethyl alcohol). Consumption of alcoholic beverages is increasing worldwide as are many of the undesirable consequences of heavy drinking and drunkenness. The effects produced by alcohol depend on the amounts consumed and the speed of drinking. Small quantities cause euphoria and feelings of well-being whereas large amounts and high blood-alcohol concentration (BAC) depress the central nervous system and cause a decrement in performance and behavior, especially when skilled tasks like driving are concerned.

The various sections of this chapter reflect different areas of interest for both forensic scientists and clinical and forensic toxicologists. The acute effects of alcohol are major concerns for motor and cognitive functioning, which is important for traffic safety because alcohol intoxication and drunkenness are incriminated in many fatal crashes. Enforcement of drinking and driving laws throughout the world depends to a large extent on the concentration of alcohol measured in a specimen of blood, breath, or urine obtained from the suspect. This kind of "chemical testing" to produce evidence for prosecution requires the use of highly reliable analytical methods to guarantee legal security for the individual. The widespread adoption of concentration per se laws for driving under the influence of alcohol tends to create a razor sharp difference in penalty for those close to the statutory limit. Small analytical or pre-analytical errors might make the difference between acquittal or punishment in borderline cases.

In addition to details of the analytical methods used to measure alcohol in body fluids, knowledge is also required about the disposition and fate of alcohol in the body and the factors influencing absorption, distribution, and elimination processes. Alcohol also tops the list of drugs encountered in post-mortem toxicology. Although the methods of analysis are the same as for living subjects, making a correct interpretation of the results is often problematic. When dealing with autopsy specimens, various artifacts can arise because of the poor quality of blood and body fluid specimen, post-mortem diffusion and redistribution, sampling site differences, and the risk of post-mortem synthesis owing to microbial activity.

Judging whether a person drinks too much alcohol is not always easy because many people deny that they have a drinking problem. This complicates making an early diagnosis and commencement of treatment for those at greatest risk of becoming dependent on alcohol. Clearly there is an urgent need to develop more objective ways to verify overconsumption of alcohol. Considerable research effort has been devoted to evaluate biochemical tests with enough sensitivity and specificity to detect hazardous drinking before this escalates to the point of causing organ and tissue damage. The final section of this chapter describes recent advances in the field of alcohol biomarkers that are intended to disclose both acute and chronic consumption of alcohol as well as relapse after a period of rehabilitation.

5.1 MEASURING ACUTE ALCOHOL IMPAIRMENT

Christopher S. Martin, Ph.D.

Western Psychiatric Institute and Clinic, Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

This section reviews impairment produced by alcohol consumption, and issues in the measurement of such impairment. Motor and cognitive impairment produced by alcohol intoxication has been noted for centuries, and is apparent to almost everyone who lives in an alcohol drinking society. The effects of alcohol consumption on behavior, cognition, and mood have been reviewed by several authors in the scientific literature.¹⁻⁴ Unlike previous reviews, this section focuses on medical and forensic aspects of the topic, with a particular emphasis on impairment testing.

Impairment and its consequences are major reasons for forensic and medical interest in alcohol consumption. The assessment of impairment caused by acute alcohol intoxication is important for forensic, research, and clinical applications. At the same time, the determinants of impaired performance are complex, and are influenced by numerous pharmacological, motivational, and situational factors. Impairment also is extremely variable between persons. While obvious at extreme levels, alcohol-related impairment raises a number of difficult measurement issues. Although many impairment tests have adequate properties in the laboratory, assessments used in field applications have important limitations.

This section begins with a review of the acute effects of alcohol on behavioral and cognitive functioning. Emphasis is given to the effects of alcohol on speech and on the functioning of the vestibular system, which is centrally involved in balance control and spatial orientation. Next, individual differences in impairment are examined. This is followed by a description of how impairment is related to the time course of alcohol ingestion. The effects of rising vs. falling blood alcohol concentrations (BACs) and acute tolerance are discussed. The behavioral correlates of a hangover are reviewed. Then we discuss the ideal characteristics of impairment tests, followed by a description of the actual characteristics of impairment tests when evaluated in laboratory and field settings.

5.1.1 Behavioral Correlates of Acute Intoxication

This section reviews the effects of alcohol on motor coordination and cognitive performance. Most “behavioral” correlates of intoxication involve both motor control and cognitive functioning. As will be seen, the effects of alcohol are not uniform; impairment varies across different types of behavioral functions. Two areas of functioning that are sensitive to alcohol impairment and assessed in field sobriety tests are described in some detail: speech and vestibular functioning. In addition, this section describes individual differences in alcohol impairment related to age, gender, and alcohol consumption practices.

5.1.1.1 Motor Control and Cognitive Functioning

Alcohol functions as a general central nervous system depressant, and affects a wide range of functions. To the observer, one of the most apparent effects of alcohol consumption is on motor control, particularly behaviors that require fine motor coordination. Other well-known effects of alcohol involve decrements in the cognitive control of behavioral functioning, especially the ability to perform and coordinate multiple tasks at the same time. Research has assessed the effects of alcohol on numerous performance tasks. Almost all of these tasks involve both cognitive and motor

control components, although tasks differ in the complexity of the motor and cognitive functioning required for performance.

Reaction Time

Some of the most basic performance tasks investigated in the literature are simple reaction time (RT) tasks, in which subjects must push a button as quickly and accurately as possible in response to a stimulus. Baylor et al.⁵ found no effects of alcohol on simple RT at BACs of 100 mg/dL, but did find effects at very high BACs near 170 mg/dL. Taberner⁶ found no effect of a low dose of 0.15 g/kg alcohol, and a small effect at a dose of 0.76 g/kg alcohol. Maylor et al.⁷ found a small effect of alcohol on simple RT at a dose of 0.64 g/kg alcohol. Linnoila et al.⁸ did not find effects of alcohol on simple RT, even though other types of performance were impaired at this dose. Although the findings are somewhat variable, simple RT appears to be relatively insensitive to alcohol consumption.

Other research has examined choice RT tasks, in which subjects are required to respond using two or more buttons in response to different stimuli. Such tasks involve motor speed as well as cognitive functions involved in categorizing a stimulus and choosing a response. Few differences were seen by Fagan et al.⁹ on a six-choice RT procedure. Golby¹⁰ found no effects of alcohol on two different choice RT tasks. Other studies have found rather small or inconsistent effects of alcohol on choice RT.^{7,11} Overall, there is not consistent evidence that alcohol affects the performance of choice RT tasks in the range of BACs studied in laboratory experiments.

The research literature contains a number of studies that have examined the effects of alcohol on tracking performance, that is, the ability of subjects to move a pointer to track a moving target. Tracking tasks require fine motor control and coordination of the hands and eyes at a rapid speed. There is consistent evidence that alcohol significantly impairs tracking performance. Beirness and Vogel-Sprott¹² found that alcohol affected tracking performance at BACs above 50 mg/dL; this effect has been replicated in numerous studies by Vogel-Sprott and colleagues. Wilson et al.¹³ found that BACs peaking at 100 mg/dL produced tracking impairments for 120 minutes after drinking relative to placebo. The effects of alcohol on tracking performance have been found by several other authors.^{8,11,14,15}

Dual-Task Performance

Alcohol impairment is found consistently during dual-task performance, when subjects are required to perform multiple tasks simultaneously. When subjects were required to perform a tracking task and an RT task at the same time, Connors and Maisto¹¹ found that alcohol reduced tracking but not RT performance. Using a similar procedure, Maylor et al.¹⁴ found that alcohol affected RT but not tracking. Differences between these two studies in the task that was affected may have been due to instructions or task demands that led subjects to select one of the two tasks as primary, leading to performance deficits on the secondary task. Niaura et al.¹⁶ combined an RT task with a task requiring the subject to circle target characters on a printed sheet, and found that alcohol produced deficits on both tasks relative to placebo. Other researchers have used computerized divided-attention tasks, which require subjects to perform multiple functions simultaneously. Mills and Bisgrove¹⁷ found that divided-attention performance (responding to numbers on central and peripheral monitors by pushing different buttons) was impaired after 0.76 g/kg alcohol, but not after a lower dose of 0.37 g/kg alcohol.

The performance of multiple challenging tasks is thought to require the utilization of a large amount of attention, defined as limited-capacity cognitive resources that are required for effortful processing. The demonstration that alcohol produces dual-task performance deficits is consistent with the idea that alcohol produces impairment, in part, by reducing the available amount of limited-

capacity attentional resources. A similar “attention allocation” model was proposed by Steele and Josephs.¹⁸ These authors found that alcohol produced clear deficits in secondary task performance without affecting primary task performance, and suggested that alcohol serves to allocate a greater amount of attentional resources to a primary task, leading to fewer resources available for processing secondary sources of information.

Other studies of the behavioral impairment produced by alcohol have used tests designed to simulate complex real-world behaviors such as driving. Accident statistics consistently demonstrate that crash risk in the natural environment increases significantly when BACs are above 40 mg/dL.¹⁹ Automobile simulator studies generally find that the information processing and lateral guidance demands of driving are adversely affected by alcohol. Several well-designed laboratory studies have demonstrated adverse affects of alcohol on skills related to driving, beginning with BACs as low as 30 to 40 mg/dL.^{15,20} Other research with automobile simulators has examined the effects of alcohol on risk taking, defined by levels of speed, cars overtaken, and number of accidents during simulated driving. McMillen et al.²¹ did not find effects of alcohol on risk taking during a driving simulation, whereas Mongrain and Standing²² did find that alcohol increased risk taking, albeit at very high BACs near 160 mg/dL.

The effects of alcohol on performance have also been studied under conditions of actual driving. Attwood et al.²³ found that performance variables such as velocity and lane position together discriminated between intoxicated and sober drivers. Huntley found decreased lateral guidance during a driving task after alcohol.²⁴ Brewer and Sandow²⁵ studied real accidents using driver and witness testimony. Among persons who were in accidents, those with BACs above 50 mg/dL were much more likely to have been engaged in a secondary activity at the time of the accident, compared to drivers with BACs below 50 mg/dL. Overall, it appears that alcohol adversely affects several types of behavioral functions involved in driving. Driving performance is complex and determined by a number of individual and situational factors and roadway conditions. More research is needed to better understand alcohol’s effects on driving performance.

5.1.1.2 Speech

It is well known to bartenders, law enforcement personnel, and the general public that alcohol consumption can produce changes in speech production often described as “slurred speech.” Because speech production requires fine motor control, timing, and coordination of the lips, tongue, and vocal cords, it may be a sensitive index of impairment resulting from alcohol intoxication. Having subjects recite the alphabet at a fast rate of speed is a well-known field sobriety test. Laboratory research suggests that speech can be a valid index of alcohol consumption. After consuming 10 oz of 86-proof alcohol, alcoholics were found to take longer to read a passage and had more word, phrase, and sound interjections, word omissions, word revisions, and broken suffixes in their speech.²⁶ Other research with nonalcoholic drinkers found that under intoxication, subjects made more sentence-level, word-level, and sound-level errors during spontaneous speech.^{27,28} Intoxicated talkers consistently lengthen some speech sounds, particularly consonants in unstressed syllables.²⁹ The overall rate of speech also slows when intoxicated talkers read sentences and paragraphs.^{27,30}

Pisoni and Martin³⁰ examined the acoustic-phonetic properties of speech for matched pairs of sentences spoken by social drinkers when sober and after achieving BACs above 100 mg/dL. Sentence duration was increased after drinking, and pitch (loudness), while not consistently higher or lower, was more variable. The strongest effects of alcohol at the sound level were for speech sounds that require fine motor control and timing of articulation events in close temporal proximity. Intoxicated talkers displayed difficulty in controlling the abrupt closures and openings of the vocal tract required for stops and affricate closures. This resulted in long durations of closures before voiced stops (e.g., /d/, /b/), and the complete absence of closures before affricates (e.g., the /ch/ in “church”). These effects are consistent with what is known about the degree of precision of motor control mechanisms required for the articulation of different speech sounds. Pisoni and Martin³⁰

also found that listeners can reliably discriminate speech produced while sober and under intoxication. State Troopers showed higher discrimination levels than other listeners, suggesting that experience in detecting intoxication may increase perceptual abilities. The approach of some field sobriety tests that have persons recite the alphabet quickly may effectively capture the detrimental effects of alcohol on the articulation of speech sounds in close temporal proximity.

Despite the data showing effects of alcohol on speech, there are a number of limitations that make it difficult to use speech production as an index of alcohol impairment. Changes in speech have been reliably produced with blood alcohol levels above 100 mg/dL; however, the effects of lower doses have been variable;^{27–29} it is not clear whether reliable effects are produced in most persons when BACs are lower. Other types of impairment are likely to occur before speech is noticeably affected. It is not clear from the literature how motivation to avoid the detection of intoxication would affect speech production. Furthermore, the specificity of speech changes to alcohol intoxication (rather than fatigue, stress, etc.) needs further study. Finally, there is extreme variability between persons in the acoustic-phonetic properties of speech, such that it is difficult to estimate the degree of impairment without comparison samples of sober speech.³¹ Despite these limitations, the literature suggests that speech is likely to be a good screening test for impairment, which can then be determined using other measures.

5.1.1.3 Vestibular Functioning

The vestibular system serves to maintain spatial orientation and balance, and eye movements that support these functions. The vestibular system is comprised of two sets of interconnected canals that provide information about spatial orientation. Each canal is comprised of a membrane embedded with sensory hair cells, and a surrounding extracellular fluid. The otolithic canals provide information about the direction of gravity relative to the head, and thus are sensitive to lateral (side to side) head movements. This is accomplished by the fact that the membrane has a specific gravity that is twice that of the extracellular space in otoliths. Under normal conditions, the semicircular canals are sensitive to rotational movements of the head, and do not respond to lateral movements. In semicircular canals, the membrane and the extracellular fluid have the same exact specific gravity (i.e., weight by volume), such that the hair cells have neutral buoyancy and are not subject to gravitational influences.³²

Positional Alcohol Nystagmus (PAN)

Alcohol's effects on the vestibular system are seen in measures that evaluate oculo-motor control, i.e., the functional effectiveness of eye movements under different conditions. During alcohol consumption, many persons show significant nystagmus (jerkiness) in eye movements when the head is placed in a sideways position: this effect is known as Positional Alcohol Nystagmus (PAN). There are two types of PAN. PAN I is characterized by a nystagmus to the right when the right side of the head is down, and to the left when the left side of the head is down. PAN I normally occurs during rising and peak BACs, beginning around 40 mg/dL.³³ PAN II normally appears between 5 and 10 hours after drinking, and is characterized by nystagmus in the opposite directions seen in PAN I.³⁴

The mechanisms of PAN I and II have been convincingly demonstrated.³⁵ Both types of PAN are produced by the effects of alcohol on the semicircular canals, making hair cells on the membrane responsive to the effects of gravity. As alcohol diffuses throughout the water compartments of the body, it first enters the membrane space (which is richly supplied with capillary blood), and diffuses only gradually into the extracellular fluid. For a time, the alcohol concentration is greater in membrane than the surrounding fluid. Because alcohol is lighter than water, the specific gravity of the membrane will be lighter than that of the surrounding fluid during this time, making the

semicircular canals responsive to gravity and producing PAN I. The faster the rate of drinking, the faster PAN I appears.³⁶

There is a period during descending BACs in which neither PAN I nor PAN II is apparent; during this time the semicircular membrane and the surrounding fluid have achieved equilibrium, and have the same specific gravity. PAN II occurs during alcohol elimination and after the body has no measurable amounts of alcohol. During PAN II, alcohol in the semicircular canals is removed from the membrane faster than the surrounding fluid; this results in the membrane having a heavier specific gravity than the surrounding fluid, which in turn produces PAN II.

Both PAN I and II may overstimulate the semicircular canals in a manner similar to motion sickness.³⁵ It is possible that the effects of alcohol on the semicircular canals play a central role in many symptoms of intoxication, including feelings of dizziness, nausea, and the experience of vertigo known as the “bedspins.” Laboratory studies have shown that the magnitude of PAN I is associated with higher BACs,³⁶ with greater impairment in postural control, and with higher subjective intoxication ratings.³⁷ As described later, it has been speculated that PAN II is associated with hangover.³⁵

Horizontal Gaze Nystagmus (HGN)

Another type of nystagmus produced by alcohol is known as Horizontal Gaze Nystagmus (HGN). HGN is defined by jerkiness in eye movements as gaze is directed to the side, when the head is in an upright position. HGN has long been noted as an effect of alcohol, and usually becomes apparent when rising BACs reach about 80 mg/dL.³⁸ HGN is assessed by having a subject follow an object with their eyes at an increasingly eccentric angle, without moving the head; the smallest angle at which nystagmus first appears is used to assess intoxication. While nystagmus occurs in a sober state at more extreme angles of eccentric gaze, alcohol decreases the size of the angle at which it is first apparent.

As with PAN, it has been demonstrated that HGN is highly associated with the effects of alcohol, as seen in studies of oculo-motor control.³⁹ Lehti⁴⁰ reported high correlations of BACs and the angle at which nystagmus in eccentric gaze became apparent. Similar effects of alcohol have been seen when nystagmus is assessed during active and passive head movements.⁴¹ Tharp et al.⁴² quantified the slope of a regression line predicting angle of onset of nystagmus from BAC. The angle of nystagmus onset was predicted at 45° for BACs of 50 mg/dL; 40° for BACs of 100 mg/dL; and 35° for BACs of 150 mg/dL. The angle of horizontal nystagmus onset has been found to have a high level of sensitivity and specificity in predicting BACs above 100 mg/dL in an emergency room setting.⁴³ HGN appears to be pharmacologically specific to alcohol. This is not the case for other aspects of ocular control such as smooth pursuit. Smooth pursuit eye movements have proven to be much more sensitive to alcohol compared with marijuana, which has very small effects.⁴⁴ However, smooth pursuit eye movements are significantly affected by benzodiazapines, barbiturates, and antihistamines,⁴⁵ and thus cannot be said to be pharmacologically specific to alcohol. Deficits in smooth pursuit in the absence of significant BACs may indicate that a person has taken sedative drugs.

Postural control tasks are some of the most widely used measures of alcohol-related impairment in the laboratory and in the field. It is likely that the functional effectiveness of the vestibular system is an important locus of the effects of alcohol on postural control. Numerous studies have demonstrated that alcohol consumption leads to increases in sway as measured on a variety of balance platforms and similar types of apparatus, appearing in many drinkers at BACs of 30 to 50 mg/dL.^{9,13,46,47} Other research has shown that sway increases with alcohol dose,^{17,48,49} and that heavier drinkers sway less after alcohol compared to lighter drinkers.⁴⁸ The effects of alcohol become greater as the postural control task becomes more difficult, such as with eyes closed, or when the feet are in a heel-to-toe position.⁴⁹ Thus, postural control appears to be a sensitive index

of alcohol effects. However, body sway shows a great deal of individual variation in a sober condition. For this reason, the ability to detect impairment from measuring sway is limited in field settings in which sober performance measures are not available.

5.1.1.4 Individual Differences

There are large individual differences in the impairment produced by alcohol consumption. The first and most obvious difference is that persons differ in the BACs they achieve when drinking alcohol. Even when controlling for BAC, however, there are large differences between persons in their sensitivity to alcohol impairment. Perhaps the most important factor is drinking practices. Those who drink more often and in greater amounts tend to develop a greater amount of tolerance to the impairing effects of alcohol, i.e., have an acquired decrease in the degree of impairment across multiple drinking sessions. Greater impairment in light drinkers compared to heavier drinkers has been shown by numerous authors using a variety of performance tasks.^{4,48,50}

There are also gender differences in some aspects of alcohol pharmacokinetics. On average, women achieve significantly higher BACs than men when drinking the same amount of alcohol because of mean gender differences in body weight and body fat,⁵⁰ and because females tend to have lower levels of gastric alcohol dehydrogenase.⁵¹ Some research with women has found greater alcohol elimination rates⁵² and greater sensitivity to alcohol effects^{53,54} during the mid-luteal and ovulatory phases of the menstrual cycle compared to the follicular phase. Other research, however, has not replicated these findings.^{16,55,56}

Some laboratory studies have examined whether males and females differ in their sensitivity to alcohol. Mills and Bisgrove¹⁷ found no gender differences in a divided-attention task after a low dose of alcohol, but greater impairment in females at a higher dose. However, in this study women achieved higher BACs, and reported less alcohol consumption compared to men. Burns and Moskowitz⁵⁷ found no significant gender differences in a series of motor and cognitive impairment tasks. When controlling for BACs, Niaura et al.¹¹ found few gender differences in psychomotor and cognitive responses to alcohol. Other research that controlled for gender differences in BACs and drinking practices has found few gender differences in response to alcohol.⁵⁸ Overall, when controlling for BACs and drinking practices, gender differences in alcohol impairment have not been demonstrated.

Little research has examined differences in alcohol impairment that are related to age. Using groups with fairly equivalent drinking practices, Parker and Noble⁵⁹ found that older subjects (over 42 years old) had more deficits on abstracting and problem solving after alcohol consumption compared to younger subjects. Linnoila et al.⁸ found a trend towards increased impairment in subjects who were 25 to 35 years old, compared to those 20 to 25 years old. Other studies have also found age-related increases in psychomotor impairment in humans,^{60,61} and in animals,⁶² even when BACs and drinking practices were equivalent in older and younger groups. Although there appears to be an increase in sensitivity to alcohol's effects with advancing age, there are few studies, and most suffer from small sample sizes. Because age effects appear to occur even when BACs and drinking practices are controlled, some have speculated that age-related increases in alcohol impairment reflect the effects of aging on vulnerability of the central nervous system to alcohol's effects.⁶²

5.1.2 Time of Ingestion

The effects of alcohol tend to vary dramatically over the time course of a drinking episode. An analysis of how the effects of alcohol change over time provides a clearer understanding of alcohol-related impairment. This section reviews differences in the effects of alcohol during the rising and falling limbs of the BAC curve, the phenomenon of acute tolerance, and post-drinking hangover.

5.1.2.1 Rising and Falling Blood Alcohol Concentrations

Researchers and clinicians have long noted that alcohol's effects are often biphasic during a drinking episode.⁶³ "Biphasic" refers to the fact that stimulant effects of alcohol tend to precede sedative alcohol effects during a drinking episode.^{64,65} There are substantial individual differences in the magnitude of stimulant effects of alcohol and the BACs at which they occur.^{66,67} Alcohol's stimulant effects are reflected in increased motor activity, talkativeness, and euphoric or positive mood at lower doses and during rising BACs.^{67,68} Stimulant effects have been assessed in humans using a variety of psychophysiological, motor activity, and self-report measures,^{65,66,69} and in animals using measures such as spontaneous motor activity.^{63,70} Stimulant effects are present in some drinkers at BACs as low as 20 to 30 mg/dL, and may persist on the rising BAC limb well past 100 mg/dL.^{63,65} Some current theories hold that stimulant effects reflect alcohol's reinforcing qualities, and that the magnitude of stimulant effects will predict future drinking and the development of alcohol dependence.^{71,72}

Some research suggests that the rate of change of rising BACs helps determine the degree of alcohol effects. A faster rise of ascending BACs is associated with greater euphoria and intoxication,^{71,73-75} as well as increased behavioral impairment.^{11,76} It is interesting to speculate that the drinking patterns shown by many heavy drinkers and alcoholics may reflect an attempt to produce a rapid rise in BACs. These patterns include gulping drinks, drinking on an empty stomach, and using progressively fewer mixers to dilute distilled spirits.

Sedative effects of alcohol usually occur at higher BACs and on the descending limb of the BAC curve. Sedation has been measured in humans using EEG patterns and self-reports of anesthetic sensations and dysphoric mood,^{64,74,77} and in animals with low motor activity and the onset of alcohol-induced sleep.^{78,79} Robust sedative effects tend to first appear at peak BACs near 60 to 80 mg/dL in many drinkers, although in persons with higher tolerance sedative effects are not apparent until BACs are above 100 mg/dL.^{49,64,65} Sedative effects of alcohol are negatively correlated with drinking practices, and lower levels of sedation after alcohol consumption may characterize persons at increased risk for the future development of alcoholism.⁷⁹⁻⁸¹

Research has clearly demonstrated that alcohol-related impairment is greater on the ascending compared to the descending limb of the BAC curve. This finding appears consistently across different doses and impairment tests. The most straightforward explanation for this effect is acute tolerance.

5.1.2.2 Acute Tolerance

There are many different types of tolerance identified by researchers.⁵⁰ Metabolic tolerance refers to an acquired increase in the rate of alcohol metabolism. Functional tolerance can be defined as an acquired decrease in an effect of alcohol at a given BAC. There are several different types of functional tolerance. Chronic tolerance refers to an acquired decrease in an effect of alcohol across multiple exposures to the drug. This section focuses on acute tolerance, defined as a decrease over time in an effect of alcohol within a single exposure to alcohol, which occurs independently of changes in BAC.

Acute tolerance is one of the most robust effects that occur in laboratory alcohol administration research. In 1919, Mellanby⁸² demonstrated that effects of alcohol were greater during the rising compared to the falling limb of the BAC curve, a phenomenon known as the "Mellanby Effect." A number of laboratory studies in humans and animals have replicated the Mellanby effect using numerous measures, such as motor coordination, self-reported intoxication, sleep time, and body temperature.^{12,83-85}

One early question raised about the Mellanby effect was whether it was the result of a methodological artifact in the measurement of alcohol concentration in blood. Venous BAC, which is sampled for alcohol measurement, is known to lag behind arterial BAC during the ascending limb

of the BAC curve, before the distribution of alcohol throughout body water compartments is complete. It is arterial blood that is closest to brain levels of alcohol. Thus, some wondered whether the Mellanby effect was an artifact because it actually compared impairment at different concentrations of alcohol in the brain.

It has been established, however, that acute tolerance and the Mellanby effect occur beyond any differences between arterial and venous BAC. First, the Mellanby effect is robust when BACs are assessed via breath alcohol; breath measures are closer to arterial than to venous BACs during the ascending limb of the BAC curve. Second, researchers have demonstrated the presence of acute tolerance using numerous alternative methods. When BACs are at a steady state, acute tolerance has been demonstrated by decreases in the effects of alcohol that occur over time.^{13,86} Furthermore, the rate of decrease in alcohol effects are significantly greater than the rate of decrease in descending BACs.^{87–89} Another demonstration of acute tolerance comes from social drinkers who report themselves as feeling completely sober when descending BACs are substantial (e.g., 30 to 50 mg/dL).⁸⁷ Investigators have demonstrated that decreased effects over time within an exposure to alcohol are not due to practice or other repeated-measures effects.^{90–92}

In some models, acute tolerance occurs in a linear fashion as a function of the passage of time, independent of alcohol concentration.⁸⁹ Others have proposed that acute tolerance is concentration dependent.⁹³ Even in this latter model, the passage of time is critical; alcohol concentration simply influences the rate of recovery over time. Martin and Moss⁸⁷ found that at both higher and lower doses of alcohol, the magnitude of the Mellanby effect was highly correlated with the amount of time between the ascending and descending limb measurements. Clearly, the amount of impairment and intoxication shown during a drinking episode is not only affected by the level of BAC, but also by the amount of time alcohol has been in a person's system.

Vogel-Sprott and colleagues have published a large body of research that demonstrates that the degree of acute tolerance development is influenced by rewards and punishments, i.e., the consequences of non-impaired and impaired performance.⁹⁴ These investigators have demonstrated that acute tolerance to the impairment produced by alcohol increases when non-impaired performance leads to financial reward or praise.^{12,95} One way to interpret these findings is in terms of motivation to show non-impaired performance. When an intoxicated motorist is stopped for questioning and/or field sobriety tests, that person will be highly motivated to show non-impaired behavior. While such attempts at appearing sober will be unsuccessful when BACs are sufficiently high, it is likely that many motorists avoid the detection of intoxication at substantial BACs by being highly motivated. Unfortunately, the same motorists may again show substantially impaired performance after the immediate contingency of detection and arrest are removed. Most of the laboratory impairment studies reviewed here did not adequately control for or study the impact of high motivational levels on the obtained results. For this reason, it is likely that the magnitude of impairment observed in many laboratory studies is greater than would be obtained in a field setting.

5.1.2.3 Hangover

Hangover has received relatively little attention in the scientific literature, but it can certainly produce alcohol-related impairment. Hangover is an aversive state typically experienced the morning after a heavy drinking bout, which is characterized by dysphoric and irritable mood, headache, nausea, dizziness, and dehydration. Sufficiently heavy drinking produces self-reported hangover symptoms in most persons, but there appears to be large individual differences in the occurrence, severity, and time course of perceived hangover that are independent of drinking practices.⁹⁶

Studies reported in the literature are contradictory concerning whether hangover is accompanied by behavioral impairment. Several early studies found no performance impairment when BACs were at or close to zero.^{97,98} Myrsten and colleagues⁹⁹ tested a variety of behavioral impairment measures 12 hours after subjects consumed a dose of alcohol producing mean BACs near 120 mg/dL. Morning BACs in this study averaged 4 mg/dL. Most measures showed no impairment,

but hand steadiness was detrimentally affected. Collins and Chiles¹⁰⁰ gave impairment tests before an evening drinking session, after alcohol consumption, and again after subjects had slept 4 to 5 hours. Subjects were affected on the performance tests during acute intoxication, and they reported significant levels of hangover during the morning session. Despite these methodological strengths, there were no clear-cut performance impairing effects of hangover in this study.

Some other research indicates that hangover is accompanied by impairment in behavioral and cognitive functioning. One experiment found that after high peak BACs of about 150 mg/dL, there was an average 20% decrement on a simulated driving task 3 hours after BACs had returned to zero.¹⁰¹ Yesavage and Leirer¹⁰² examined hangover effects in Navy aircraft pilots 14 hours after drinking enough alcohol to produce BACs of about 100 mg/dL, using a variety of flight simulator measures. Significant detrimental effects of hangover were found for 3 of 6 variance measures and 1 of 6 performance measures. Similarly, other studies have found impairment due to hangover on only some of the tests employed in the research.^{103,104}

Some have speculated that the nausea and dizziness of hangover may be associated with PAN II, an eye movement nystagmus that occurs during falling BACs and after measurable alcohol has left the system.³⁵ PAN II reflects the sensitivity of semicircular canal receptors to gravity, which also produces feelings similar to motion sickness. More research is needed to address the role of vestibular functioning in hangover.

Inconsistencies in the hangover literature probably reflect the fact that behavioral impairment during hangover is influenced by numerous factors, including sleepiness, fatigue, mood, and motivation to behave in a non-impaired manner. Moreover, there are individual differences in the frequency and duration of hangover, even among persons with similar drinking practices. For many persons, the BACs required to produce subsequent hangover may be greater than those typically obtained in laboratory studies. Hangover effects are poorly characterized, and are an important topic for further research.

5.1.3 Impairment Testing

5.1.3.1 *Ideal Characteristics of Impairment Tests*

The strengths and weaknesses of impairment tests used in the laboratory and the field are best evaluated in contrast with their ideal properties. There are a number of concepts that can be used to describe the characteristics of impairment tests, including scaling of results, applicability to field settings, reliability, validity, sensitivity, and specificity.¹⁰⁵

Impairment tests differ in the scaling of results, that is, the nature of the scores or outcomes of a test. Results may be binary (impaired or not), ordinal rankings (low, medium, or high impairment), or quantitative scores. The need for precision of results depends upon the testing application. When used primarily as a screening tool for other sobriety tests or a BAC assessment, binary scores or ordinal rankings may be adequate. In other instances, continuous scores are desirable because they inform about the level of impairment.

Applicability to field settings is important for any impairment test used in law enforcement. One requirement is that a test must have adequate measurement properties in a field setting. A test may have demonstrated reliability and validity in the laboratory, but these properties may or may not generalize to field settings. Field applications involve a loss of control over numerous variables that can influence testing. Reliability and validity properties in the field may be far different from the laboratory, in part because data from a known sober condition are not available for comparison.

There are several other important considerations in relation to field settings. Ideally, a test must be easily administered in a standard way by test administrators, and readily understood by test takers. The level of technical skill required for administering the test, collection of data and interpretation of results should be acquired with a reasonably short duration of training. Any required instrumentation should not require extensive maintenance, and should not be easily subject to

interference by test takers. Importantly, impairment tests must have credibility with law enforcement officers and the wider criminal justice system. Whereas sobriety tests are often used as a preliminary screen for reasonable cause in BAC testing, they nevertheless must be generally acceptable to prosecutors, judges, and juries.

Reliability

Reliability refers to the extent to which a test provides a result that is stable or repeatable. That is, a reliable test is one that will yield a similar result across multiple testings in the same person (test-retest reliability), or across multiple test administrators or raters examining the same person (inter-rater reliability). An ideal impairment test should be reliable across testings in a sober person, i.e., it would reveal a stable baseline for non-impaired performance. Furthermore, an ideal test should show reliability across testings in an intoxicated person. That is, multiple tests taken at the same level of impairment would show relatively little variation in the obtained scores. Reliability is a key feature of any impairment test. If obtained scores are not reliable, the results may be caused by factors other than impairment, such as variation in test administration or scoring.

Validity

Validity concerns the extent to which a test accurately measures what it was intended to measure. The validity of impairment tests refers to the extent to which these tests assess alcohol-related impairment, rather than other factors. Face validity refers to the extent to which law enforcement personnel and test takers believe that a test does measure alcohol impairment; many field sobriety tests have high levels of face validity. Concurrent validity refers to the extent to which an impairment test shows expected associations with other tests known to measure impairment, and with BACs. Construct validity refers to the adequacy and explanatory power of scientific concepts such as alcohol impairment. If alcohol-related impairment is highly variable across different behaviors, this will reduce the validity of any one test in measuring such a diffuse concept.

A test can be reliable but not valid. For example, a person's height can be measured in a highly reliable fashion, but the observed results would be an invalid index of alcohol impairment. In contrast, some level of reliability is needed in order for a test to show validity. If an impairment test has no reliability, it cannot be valid. The degree to which reliability is imperfect tends to place an upper limit on the degree of validity that can be shown by a test.¹⁰⁶

Sensitivity

Sensitivity refers to the ability of a test to detect impairment, and can be defined as the proportion of impaired persons (as determined by some other established measure) who are classified as impaired by a test. Thus, insensitive tests can allow persons who are impaired to escape detection (a false negative test result). Whereas signs of intoxication are evident from test results in almost all persons when BACs become sufficiently high, many measures do not detect impairment when BACs are below 100 mg/dL. Among some heavy drinkers, many tests will be insensitive to BACs well above 100 mg/dL. In some cases, there probably is little impairment to detect when a test does not reveal impairment. In other cases, however, impaired performance is likely present, but a test is not sensitive enough to detect it.

Specificity

The specificity of an impairment test refers to the extent to which the results reflect alcohol impairment and not other factors such as fatigue, stress, and individual differences in cognitive and motor skills. A highly specific test will not be much influenced by changes in parameters other

than alcohol impairment. An example of high test specificity in biological measurement is seen for BACs, where existing instrumentation allows assessment of alcohol in blood and breath that is not affected by closely related chemical compounds such as acetate, acetaldehyde, or acetone. Tests with low levels of specificity will lead to a high proportion of false positive test identifications. That is, results for a non-specific test will often suggest that a person is impaired when they actually are not impaired (as measured by BAC or other tests). Thus, low specificity in impairment testing can lead to an inefficient expenditure of law enforcement resources.

An important issue in evaluating the sensitivity and specificity of impairment tests is whether measures of sober performance are available. Many tests show large individual differences in sober performance.^{13,94} In laboratory research tests, sensitivity and specificity are evaluated by comparing a subject's performance at different BACs with their test performance when sober, usually before drinking begins. However, sensitivity and specificity are more difficult to achieve in the field, when sober baseline performance data are not available. Therefore, tests that are known to have less variation among sober persons are preferable for field settings.

When developing cutoff scores on impairment tests, increased sensitivity almost always comes at the expense of decreased specificity, and vice versa. The "best" cutoff score for the definition of impairment depends upon the relative importance of sensitivity and specificity in a given application, as well as the estimated base rate of impairment in the population that will be tested.¹⁰⁶ The choice of an appropriate cutoff score for an impairment test must be based on an understanding of these factors.

5.1.3.2 Characteristics of Existing Field Sobriety Tests

This section focuses on three field sobriety tests (FSTs) that have been standardized by the National Highway Traffic Safety Administration,¹⁰⁷ and which are widely used in the U.S. and elsewhere. In the one-leg stand test, subjects must raise one foot at least 6 in. off the ground and stand on the other foot for 30 seconds, while keeping their arms at their sides. Performance is scored on a 4-point scale, using items such as showing significant sway, using arms for balance, hopping, and putting down the raised foot. In the walk-and-turn test, subjects must balance with feet heel-to-toe and listen to test instructions. Then, subjects must walk nine steps heel-to-toe on a straight line, turn 180 degrees, and walk nine additional steps heel-to-toe, all the time counting their steps, watching their feet and keeping their hands at their sides. Performance is scored on an 8-point scale, using items such as starting before instructions are finished, stepping off the line, maintaining balance with arm movements, and taking an incorrect number of steps. The gaze nystagmus test assesses horizontal gaze nystagmus. The angle of onset of nystagmus is assessed for each eye. Performance is scored on a 6-point scale (3 possible points for each eye).

Some research has examined the properties of these three FSTs. In a laboratory study, *Tharp et al.*⁴² used 297 drinking volunteers with BACs from 0 to 180 mg/dL who were tested by police officers trained in the use of FSTs. Inter-rater reliability correlations for the FSTs ranged from 0.60 to 0.80, indicating an adequate level of reliability across test administrators. Test-retest correlations, examining the correspondence of FST scores on two separate occasions at similar BACs, ranged from about 0.40 to 0.75, indicating adequate test-retest reliability. All of the FSTs correlated significantly with BACs. Using all three FST test scores, officers were able to classify 81% of persons in terms of whether their BACs were above or below 100 mg/dL. Similar results using these standard FSTs in a field setting were obtained by *Anderson et al.*¹⁰⁸ However, neither of these reports provided data on the specificity and sensitivity of individual FSTs.

Few studies have reported the characteristics of individual FSTs in field settings. One study found that HGN, specifically the angle of horizontal nystagmus onset, had high levels of sensitivity and specificity in predicting BACs above 100 mg/dL in an emergency room setting.⁴³ *Perrine et al.*¹⁰⁹ examined the reliability and validity of the National Highway Traffic Safety Administration FSTs in a field setting with 480 subjects, using police officers and other trained individuals as test

administrators. Inter-rater reliability was adequate for all three FSTs. All of the FSTs were significantly correlated with BAC; however, the magnitude of these correlations was low in the case of the walk-and-turn and the one-leg stand tests. Perrine et al.¹⁰⁹ provided data on the sensitivity and specificity of each FST as a function of different levels of BAC. The data indicated that the horizontal gaze nystagmus test had excellent sensitivity and specificity characteristics. Only 3% of subjects with a zero BAC failed the horizontal gaze nystagmus test (i.e., specificity was high when referenced to a zero BAC). Sensitivity was 100% for those with BACs over 150 mg/dL, and was 81% for subjects with BACs ranging from 100 mg/dL to 149 mg/dL.

However, Perrine et al.¹⁰⁹ found that prediction of BAC was much worse using the walk-and-turn and the one-leg stand test. For the walk-and-turn test, specificity was low, in that about half of those with a zero BAC were classified as impaired. While sensitivity was fairly high (78%) at BACs above 150 mg/dL, this parameter fell below 50% for those with BACs between 80 mg/dL and 100 mg/dL. For the one-leg stand test, 30% of those with a zero BAC were classified as impaired, indicating only moderate specificity. Sensitivity was only 50% for those with BACs between 100 mg/dL and 150 mg/dL, but improved to 88% for those with BACs above 150 mg/dL.

The literature suggests that overall, FSTs such as the walk and turn, one leg stand, and horizontal gaze nystagmus test, have adequate properties for detecting impairment in field settings. These tests meet the requirements of applicability to the field, in that they can be administered in a standardized fashion, have face validity, and are understood by test takers. Training of test administrators can occur in a reasonable period of time. Results suggest that these tests can be administered reliably, and have validity in the sense that they do measure impairment due to alcohol. However, horizontal gaze nystagmus performs much better at predicting BAC than the walk-and-turn and the one-leg stand tests. While they are worthwhile, the latter two FSTs have significant limitations when used in field settings. More research is needed to determine if improved testing procedures or different cutoff scores can improve the performance of the walk-and-turn and the one-leg stand tests.

It is important to note that the properties of FSTs depend upon the threshold BACs they are supposed to detect. FSTs can be used to test impairment that occurs at BACs below a legal limit, but much of their utility depends upon their ability to determine whether a person has a BAC above that allowed by law. The FSTs described above were designed and tested in the context of the limits of 100 mg/dL that exist throughout most of the U.S. However, the limit is currently 80 mg/dL in California, and is 50 mg/dL or 20 mg/dL in many European countries. It is likely that the performance of FSTs decreases as the BAC limit decreases. More research is needed to determine whether FSTs have utility when used to detect lower BAC threshold limits.

5.1.4 Conclusions

While it is clear that alcohol impairs performance, the presence and degree of impairment depends upon a large number of individual, situational, and pharmacological factors. Moreover, impairment is not uniform across all types of behavioral and cognitive functioning. Simple behaviors, such as reaction time tasks performed in isolation, are generally insensitive to alcohol consumption. Well-practiced behaviors tend to be insensitive to alcohol except at very high doses.

Impairment is seen consistently in tasks requiring the simultaneous processing of multiple sources of information. The results from dual-performance and divided-attention tasks suggest that alcohol reduces the amount of limited-capacity attentional resources available for coordinating multiple tasks. These results provide an important view of how alcohol can produce accidents and injuries. For example, the intoxicated motorist may perform with only moderate impairment on a well-known route with little traffic. However, when a situation arises that requires the simultaneous processing of multiple sources of information, such as avoiding an unexpected obstacle in traffic, large performance deficits may occur.

Alcohol also produces deficits in activities that require fine motor control at high rates of speed. One of the most sensitive behavioral measures of impairment found in the literature is tracking

performance, which requires rapid small adjustments in the muscles of the hands and eyes, and a high level of hand-eye coordination. Tracking performance is an important aspect of impairment, in part, because it is central to the lateral guidance of a motor vehicle. Another type of behavior sensitive to alcohol is speech, which requires fine motor control, timing, and coordination among the lips, tongue, and vocal cords at a high rate of speed.

Impairments in eye movements and balance after drinking primarily reflect alcohol's effects on the brain's vestibular system. Alcohol is a small water-soluble molecule that readily diffuses throughout the brain, and impairment is often described in terms of alcohol's general depressant effects on all neural functions. However, impairment in vestibular functioning provides an example of specificity in alcohol's effects. The mechanisms of vestibular impairment have been fairly well characterized, and relate to how alcohol effects the specific physiology of this system. Vestibular functioning is relatively sensitive to alcohol's effects and important for behavioral functioning, and therefore is a logical focus of impairment testing.

There are large individual differences in the impairment produced by alcohol consumption, even when controlling for level of BAC. Several sources of these individual differences have been identified. Perhaps the most important factor is drinking practices. Those who drink more often and in greater amounts tend to develop a greater degree of chronic tolerance to the impairing effects of alcohol, i.e., have an acquired decrease in the degree of impairment across multiple drinking sessions. However, by definition, heavy drinkers tend to consume more and will be more likely to have higher BACs when tested in forensic settings. Thus, heavier drinking practices are probably not predictive of less impairment in field settings because individual differences in BACs are not controlled. Impairment tends to be greater in older adults as compared to younger adults; this effect is likely a combination of increased neural vulnerability with aging and differences in drinking practices between young and old. When controlling for BACs and drinking practices, gender differences in impairment have not been demonstrated.

The impairment produced by alcohol depends upon the time course of a drinking episode. Alcohol's effects have been described as biphasic, with initial euphoria and stimulant effects during early rising BACs, followed by dysphoria and sedative effects later on. Numerous measures of impairment are greater on the ascending compared to the descending limb of the BAC curve. This change in impairment due to limb of the BAC curve most likely reflects the phenomenon of acute tolerance, in which alcohol effects decrease over time within a drinking episode. In the prediction of impairment, the amount of time elapsed since alcohol has been in the system can be as important a variable as BAC itself.

The time course of alcohol's effects do not always end when BACs fall to zero. Sufficient drinking can produce hangover in many persons. Hangover is accompanied by impairment in behavioral functioning in some studies. Other research, however, has not found consistent effects of hangover on performance. There appear to be large individual differences in the degree of hangover effects, and their duration. Hangover effects are poorly characterized compared to other effects of alcohol, and are an important topic for further research. The demonstration of significant impairment related to hangover would suggest the need for a longer period of abstinence from alcohol use before job performance in some professions, similar to the rules often applied to airline pilots.

Field sobriety tests, such as the walk and turn, one-leg stand, and horizontal gaze nystagmus tests, can be administered in a standardized fashion and meet the requirements of applicability to the field. These tests have adequate levels of validity, in that they reliably assess functions known to reflect alcohol impairment, and correlate with BACs and other impairment measures. Levels of sensitivity and specificity appear to be fairly high for the horizontal gaze nystagmus test. On the other hand, levels of test sensitivity and specificity are adequate but somewhat low for the walk-and-turn and the one-leg stand. That is, many persons with positive BACs, including those over 100 mg/dL, will be classified as not impaired using these tests, and many persons with low or zero BACs will be classified as impaired. Furthermore, the validity of FSTs for detecting lower threshold BACs such as 50 mg/dL or 20 mg/dL remains to be established. The development of new field

sobriety tests that increase the accurate assessment of impairment would be of great benefit in forensic applications.

5.2 UPDATE ON CLINICAL AND FORENSIC ANALYSIS OF ALCOHOL

Alan Wayne Jones, Dr.Sc.¹ and Derrick J. Pounder, M.D.²

¹Department of Forensic Toxicology, University Hospital, Linköping, Sweden

²Department of Forensic Medicine, University of Dundee, Scotland, U.K.

5.2.1 Introduction

Alcohol is the world's favorite recreational drug and moderate drinking has few untoward effects on a person's health and well-being.¹ Indeed, drinking small amounts of alcohol helps to relax people and relieve their inhibitions.² Moreover, scores of studies testify to the efficacy of small doses of alcohol, such as one to two glasses of red wine daily, as an effective prophylactic treatment for cardiovascular diseases such as ischemic stroke and heart failure.^{1,3,4} In contrast, heavy drinking and drunkenness constitute major public health problems for both the individual and society.^{5,6} Binge drinking is the cause of deviant behavior and is closely linked to family violence. Many of those who seek help from hospital casualty and emergency units are under the influence of alcohol.⁷⁻¹⁰ High blood alcohol concentrations (BACs) are a common finding in all out-of-hospital deaths, especially in victims of suicide and drowning.¹¹⁻¹³ Accordingly, the determination of alcohol in body fluids is the most frequently requested service from forensic science and toxicology laboratories worldwide.¹⁴⁻¹⁷

The role of alcohol intoxication in traffic crashes and deaths on the roads is well recognized, which has led to the creation of punishable BAC limits for driving.¹⁸⁻²¹ Measuring a person's blood- or breath-alcohol concentration (BrAC) furnishes compelling evidence for the prosecution case and, if above the legal limit, a guilty verdict is virtually guaranteed.^{20,21} People who perform skilled tasks like operating machinery or other safety-sensitive work should avoid drinking alcohol for obvious reasons. Indeed, alcohol use in the workplace is regulated by statute in the U.S. (1991 Omnibus Transportation Employee Testing Act), and similar legislation can be expected in other countries.²² The threshold BAC in connection with workplace testing is set at 20 mg/dL (0.02 g/210 L in breath), below which no action is taken. However, drinking on duty or having a BAC above 40 mg/dL (0.04 g/210 L of breath) is prohibited and the offending individual will be removed from participating in safety-sensitive work and risks being dismissed.²²

The punishment for driving under the influence of alcohol (DUI) includes a stiff fine, suspension of the driving license, and sometimes a period of imprisonment. Moreover, the validity of accident and insurance claims might be null and void if a person has been drinking and the BAC was above some threshold limit. The statutory alcohol limits for driving differ from country to country and

Table 5.2.1 Statutory BAC Limits for Driving in Different Parts of the World Expressed in Different Concentration Units

Country	g/100 mL	g/L (mg/mL)	mg/100 mL	mmol/L ^a
U.S. and Canada	0.08	0.80	80	17.3
Australia (most states)	0.05	0.50	50	10.9
U.K. and Ireland	0.08	0.80	80	17.3
Sweden and Norway ^b	0.02	0.20	20	4.3
Most EU countries	0.05	0.50	50	10.9

^a Derived as [(mg/L)/46.07], where 46.07 is the molecular weight of ethanol to give mmol/L.

^b The concentration unit mass/mass is used (mg/g or g/kg) so 0.02 mg/g = 0.21 mg/mL because the density of whole blood is 1.055 g/mL on average.

this seems to depend more on political forces rather than traffic safety research and studies of crash risk as a function of BAC.^{20,21} Table 5.2.1 lists the current legal alcohol limits in blood for driving in various parts of the world. These critical values are so-called per se concentration limits and additional proof that the person was under the influence of alcohol is unnecessary for a successful prosecution.²⁰

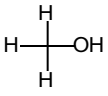

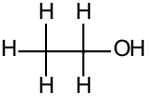

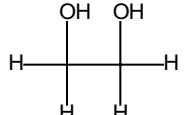

The evolution of methods for determination of alcohol in body fluids has a long history and the first wet-chemical oxidation procedures were introduced more than 100 years ago.^{17,23,24} Because of ease of collection and the larger volumes available, urine was the first biological specimen to be used for analysis of alcohol in clinical investigations. Finding a high concentration of alcohol in a sample of urine was a more objective test to verify clinical signs and symptoms of drunkenness. Moreover, many studies showed that the concentration of alcohol was highly correlated with subjective and objective measures of alcohol influence and performance decrement. The methods available for analysis of alcohol in biological specimens have become considerably refined and exhibit high sensitivity, specificity, accuracy, and precision.^{14,15,25}

Fast and reliable analytical methods are needed in emergency situations, such as when a patient is admitted unconscious smelling of alcohol. One needs to distinguish gross intoxication from head trauma, which might require immediate surgery to remove intracranial blood clots.^{26–28} Analytical methods used at hospital clinical laboratories need to differentiate ethanol intoxication from the impairment caused by drinking more dangerous alcohols like methanol and ethylene glycol.^{29–31}

Table 5.2.2 gives basic chemical information about the alcohols most commonly encountered in clinical and forensic toxicology, namely, ethanol, methanol, and ethylene glycol. Depending on the concentration of methanol and ethylene glycol in blood, the emergency physician has to make a life saving decision to treat the poisoned patient with invasive therapy and antidotes.^{32–34} This might entail administration of ethanol by intravenous infusion of a 10% solution to reach a BAC of 100 to 120 mg/dL and maintain this level for several hours. More recently the drug fomepizole (4-methyl pyrazole) has been introduced as an alternative treatment and is more suitable for use in young children or those with liver dysfunction.^{32,35} Both ethanol and fomepizole function as competitive inhibitors of hepatic alcohol dehydrogenase (ADH), and help to prevent the conversion of methanol and ethylene glycol into their toxic metabolites, formaldehyde and formic acid and glycolic and oxalic acids, respectively.^{35,36} The methanol and ethylene glycol remaining unmetabolized can be removed from the blood by hemodialysis and bicarbonate is usually administered to counteract acidosis caused by the acid metabolites of these more toxic alcohols.³³ The various treatment strategies currently available for dealing with methanol and ethylene glycol poisoning have been extensively reviewed.^{29–36}

The diagnosis of drunkenness has broad social-medical ramifications and great care is needed when forensic practitioners and others are called upon to interpret results of analysis and draw conclusions about the degree of alcohol influence and the consequences for behavioral impairment. This chapter provides an update of clinical and forensic-medical aspects of alcohol analysis in body fluids, and research into the disposition and fate of alcohol in the body are also covered. In post-

Table 5.2.2 Characteristic Features of Three Common Aliphatic Alcohols (Methanol, Ethanol and Ethylene Glycol) Often Encountered in Forensic and Clinical Toxicology

Property	Methanol	Ethanol	Ethylene Glycol
CAS-number ^a	65-46-1	64-17-5	107-21-1
Molecular weight	32.04	46.07	62.07
Molecular formula	C ₂ H ₄ O	C ₂ H ₆ O	C ₂ H ₆ O ₂
Chemical formula	CH ₃ OH	CH ₃ CH ₂ OH	(CH ₂ OH) ₂
Structure	Primary aliphatic alcohol	Primary aliphatic alcohol	Dihydroxy aliphatic alcohol (diol)
Structural formula			
Common name	Wood alcohol	Beverage or grain alcohol	Antifreeze solvent
Boiling point, °C	64.7	78.5	197
Melting point, °C	−95.8	−114.1	−13
Density, at 20°C	0.791	0.789	1.11
Water solubility	Mixes completely	Mixes completely	Mixes completely
Main metabolites	Formaldehyde and formic acid	Acetaldehyde and acetic acid	Glycolaldehyde, glycolic, glyoxylic and oxalic acid

^a CAS, Chemical Abstract Service Registry Number.

mortem toxicology, the choice of specimens, the preservation and storage, and particularly the interpretation of the results require special considerations. The role of alcohol in post-mortem toxicology with main focus on interpreting the analytical findings is covered in more detail in Chapter 5.3.

5.2.2 Specimens for Clinical and Forensic Analysis of Alcohol

5.2.2.1 Concentration Units

Unfortunately, there is no generally accepted way of reporting the results of alcohol analysis in body fluids and it is seemingly impossible to reach a consensus among scientists, scientific journals, and forensic practitioners on this issue.^{37,38} Most clinical chemistry laboratories use the International system of units (SI system) established by broad international agreement. According to this system, the standard for the unit of mass is the kilogram, the unit of volume is the liter, and the amount of substance is the mole. The concentrations of endogenous or exogenous substances in serum or plasma are therefore reported as mmol/L or μmol/L. By contrast, forensic science and toxicology laboratories report their analytical results in mass per unit volume units (mg/dL, g/L, g/dL or mg/mL) or in mass per unit mass units (g/kg or mg/g) when aliquots are weighed. The mass/mass unit is numerically less than the mass/volume unit by about 5.5% owing to the specific weight of whole blood, which is 1.055 g/mL on the average (1 mL whole blood weighs 1.055 g).³⁹ This means that a BAC of 100 mg/dL is the same as ~95 mg/100 g or 21.7 mmol/L.

5.2.2.2 Water Content of Serum and Whole Blood

The blood specimens received by forensic science and toxicology laboratories for analysis might be hemolyzed and are sometimes clotted. In contrast, the specimens analyzed at clinical laboratories usually consist of plasma or serum, that is, with the cellular elements, mainly red cells (erythrocytes), removed.⁴⁰ Because the water content of serum and plasma is higher than that of whole blood, the concentration of alcohol is also higher after removal of the red cells. Water content is a key factor controlling the distribution of alcohol in body fluids and this was recently the subject of a multicenter study in Germany.⁴¹ The results reported by the three participating

Table 5.2.3 Mean, SD, CV%, and Range of Water Content of Serum (A) and Whole Blood (B) and the Serum/Blood Ratio of Water Contents (C) Based on Measurements Made at Three Different Laboratories in Germany

Laboratory	N	Mean g%	SD g%	CV%	Range g%
(A) Serum					
Kiel	230	90.49	0.86	0.95	87.2–93.3
Köln	503	90.71	0.54	0.59	88.6–92.2
Münster	100	90.75	0.61	0.67	89.1–92.8
Combined	833	90.66	0.66	0.72	87.2–93.3
(B) Whole blood					
Kiel	230	78.35	1.44	1.83	74.8–82.9
Köln	503	78.41	1.11	1.41	75.7–83.0
Münster	100	78.14	1.28	1.63	74.9–83.3
Combined	833	78.36	1.23	1.57	74.8–83.3
(C) Serum/Blood Ratio					
Kiel	230	1.156	0.0184	1.59	1.11–1.21
Köln	503	1.157	0.0145	1.25	1.10–1.20
Münster	100	1.162	0.0187	1.61	1.08–1.20
Combined	833	1.157	0.0163	1.40	1.08–1.21

laboratories are compared in Table 5.2.3 and the values are given in mass/mass units, namely, g water per 100 g specimen.

Because this work was done at three different laboratories each using highly reliable methods based on desiccation and gravimetric analysis, there is high confidence in the results reported.⁴² To convert the results into mass/volume units, the values in Table 5.2.3 need to be multiplied by 1.055 (average density of whole blood is 1.055 g/mL).³⁹ The average serum/blood distribution ratio of water in this study was 1.157:1 and the standard deviation was 0.0163 ($N = 833$) with minimum and maximum values of 1.08 and 1.25. These results can be considered representative of people who drink and drive in Germany. Dividing the concentration of ethanol in serum by 1.16:1 gives the concentration expected in whole blood. Because plasma and serum contain the same amount of water, one expects the plasma/whole blood ratio of alcohol to be the same as the serum/whole blood ratio, as was shown empirically.⁴³ The results of alcohol analysis done at clinical chemistry laboratories should not be cited in drunken driving trials or other legal proceedings without an appropriate correction being made for the water content of the specimens or seeking expert help with interpretation of the results.^{44,45}

The mean and standard deviation of the serum/whole blood distribution ratios of water from the German study⁴¹ can be used to derive a 95% range of expected values in the relevant population as $1.16 \pm (1.96 \times 0.0163)$. Accordingly, 2.5% of individuals will have a serum/whole blood ratio above 1.19 and 2.5% will have a ratio below 1.12. Depending on requirements, more conservative values can be obtained by using the minimum and maximum values given in Table 5.2.3, namely 1.08 and 1.21.⁴¹

5.2.2.3 Blood Hematocrit and Hemoglobin

Hematocrit is defined as the percentage in a volume of whole blood represented by the red blood cells (erythrocytes) and is determined by centrifugation. The hematocrit is sometimes referred to as the packed red cell volume, and a common reference interval for healthy men is 39 to 49% compared with 35 to 45% for healthy women with wider ranges in young and elderly individuals.⁴⁰

Figure 5.2.1 Strong positive correlation between hematocrit and hemoglobin content of venous blood samples (left plot) and strong negative correlation between water content and hemoglobin (right plot).

Because the water content of plasma is greater than that of whole blood and erythrocytes, one can expect that a blood specimen with high hematocrit (e.g., donated by a male subject) will contain less water than a blood specimen from a female with low hematocrit.⁴⁶ Extreme values in hematocrit and hemoglobin are likely to be found in conditions such as anemia (low values) or polycythemia (high values).^{40,46}

Figure 5.2.1 (left graph) shows a strong positive correlation ($r = 0.96$) between blood hematocrit and hemoglobin content of whole blood specimens. The right plot shows a strong negative correlation ($r = -0.94$) between water content of whole blood and the hemoglobin content. These interrelationships will have a bearing on the plasma/whole blood and serum/whole-blood distribution ratios of alcohol in any individual case.

5.2.2.4 Alcohol Concentrations in Plasma and Whole Blood

Figure 5.2.2 shows mean concentration-time profiles of ethanol in plasma and whole blood after nine healthy men fasted overnight before drinking a bolus dose of ethanol (0.3 g/kg) diluted

Figure 5.2.2 Mean concentration-time profiles of ethanol in specimens of whole blood and plasma from nine healthy men who drank a bolus dose of ethanol 0.30 g/kg mixed with orange juice in 15 min after an overnight fast.

Table 5.2.4 Relationships between the Concentrations of Ethanol in Serum and the Expected Concentrations in Whole Blood Using Conversion Factors Based on Water Content of Serum and Whole Blood⁴¹ (the 95% range and the minimum and maximum values are also calculated)

Serum Alcohol ^a mg/100 mL	Blood Alcohol Mean mg/100 mL	Blood Alcohol 95% Range	Blood Alcohol min; max
20	17.2	16.7–17.7	16.5; 18.5
50	43.1	41.9–44.3	41.3; 46.3
80	68.9	67.1–70.9	66.1; 74.1
100	86.2	83.9–88.6	82.6; 92.6
150	129.3	125.8–132.9	123.9; 138.9
200	172.4	167.7–177.3	165.3; 185.1

^a Mean serum/blood alcohol ratio 1.16:1, standard deviation 0.0163, and minimum and maximum values 1.08 and 1.21 (see Table 5.2.3).

with orange juice.^{47,48} The plasma curves run systematically above the whole-blood curves as expected from the difference in water content of the specimens. In this study, the experimentally determined plasma/whole-blood ratios of alcohol ranged from 1.08 to 1.19.⁴⁷ In a study with drinking drivers, a mean distribution ratio of ethanol between plasma and whole blood was reported to be 1.14:1 (standard deviation 0.041).⁴⁹

Table 5.2.4 compares the alcohol concentrations in plasma or serum with values calculated by assuming a mean ratio of 1.16 and minimum and maximum values of 1.08 and 1.21 according to the above-referenced study from Germany (Table 5.2.3). The results are reported for ethanol concentrations ranging from 20 to 200 mg/100 mL.⁴¹

As discussed by Rainey,⁴⁴ whenever the concentration of alcohol in plasma or serum is used to estimate the concentration in whole blood for law enforcement purposes, it is advisable to consider the inherent variations in plasma/blood ratio of alcohol. He recommended that a conversion factor of 1.22:1 should be used, thus corresponding to mean + 2 SD from the various studies cited. This higher conversion factor seems more appropriate in forensic casework instead of using a mean value and will give a more conservative estimate of the person's BAC. In criminal law, a beyond-a-reasonable-doubt standard is necessary, whereas in civil litigation a preponderance of the evidence is sufficient to determine the outcome.

5.2.2.5 Allowing for Analytical Uncertainty

When blood samples are submitted for forensic alcohol analysis, it is a standard practice to make the determinations in replicate, always duplicate, and sometimes in triplicate.^{50–52} Finding a close agreement between the two measurements (high precision) gives added assurance that no mishaps have occurred during sample handling and analysis. Besides reporting the average result, an allowance is necessary to compensate for uncertainty (random and systematic error) in the analytical method used.^{25,51,52} This is easily done by making a deduction from the mean result to give a lower 95, 99, or 99.9% confidence interval depending on requirements.

In connection with prosecution for DUI in Sweden, besides the mean alcohol concentration, it is standard practice to report the lowest concentration of alcohol in the specimen analyzed with a probability of 99.9%.²⁵ The suspect's true BAC is therefore not less than this value with confidence of 99.9% or, in other words, there is a risk of 1:1000 of being unfair to the accused. The amount deducted from the mean of a duplicate determination is given by $[3.09 \times (SD/2^{1/2})]$ where SD is the standard deviation for a single determination using an analytical system demonstrated to be under statistical control.^{25,51} The factor 3.09 is obtained from statistical tables of the normal distribution. Although the mean result of analysis is the best estimate of a person's BAC, the deduction compensates for factors beyond the suspect's control and gives the benefit of the doubt

in those instances when the true BAC is close to the legal limit for driving. In such borderline cases, the risk of reporting a result, which in reality was just below the legal limit, as being above the limit is only 1 in 1000. The use of a deduction has practical significance only for individuals with a BAC at or near the critical legal limit for driving.

This use of a deduction is not customary in clinical chemistry laboratories, where single analyses are usually made.^{53,54} Instead, most clinical chemistry laboratories compare their results with established reference ranges derived from previous experiences with specimens from healthy individuals depending on age and gender.⁵³ The result for the patient sample is compared with a so-called “normal range” in a comparable population of healthy individuals.⁵⁴ The imprecision of the analytical methods are monitored from the expected coefficient of variation (CV%) derived from analysis of calibration standards or spiked biological specimens analyzed along with the unknowns.^{40,53}

5.2.3 Measuring Alcohol in Body Fluids

5.2.3.1 Chemical Oxidation Methods

The first quantitative method of blood-alcohol analysis to gain general international acceptance in forensic science and toxicology was published in 1922⁵⁵ and became known as the Widmark micromethod (developed by Erik M.P. Widmark of Sweden). A specimen of capillary blood (100 mg) was sufficient for making a single determination and this could be obtained by pricking a fingertip or earlobe. Ethanol was determined by wet-chemistry oxidation with a mixture of potassium dichromate and sulfuric acid in excess. The amount of oxidizing agent remaining after the reaction was determined by iodometric titration.⁵⁵ Specially designed diffusion flasks permitted extraction of ethanol from the biological matrix by heating in a water bath for a few hours at 50°C. Ethanol and other volatiles were removed from the biological matrix by vaporization and oxidized within the flask and after cooling and addition of potassium iodide the final titrimetric analysis was done in the same flask. However, Widmark's method was not totally specific for determination of blood ethanol because other volatiles, if these were present, such as acetone, methanol or ether, were also oxidized by the reagents and gave false high ethanol readings. The likelihood of potential interfering substances (e.g., acetone) could be tested by making a qualitative analysis of urine by adding various chemical reagents and looking for any characteristic color change such as that seen with high levels of ketones.⁵⁶

By the 1950s the chemical oxidation methods were improved by monitoring the end point by photometry rather than by volumetric titration.^{17,56} Today, analytical procedures based on wet-chemistry oxidation reactions are virtually obsolete in clinical and forensic laboratories for determination of alcohol in body fluids.¹⁴ The history, development, and application of chemical oxidation methods of alcohol analysis have been well covered in several review articles.^{17,57–59}

5.2.3.2 Enzymatic Methods

Shortly after the enzyme alcohol dehydrogenase (ADH) was purified from horse liver and yeast in the early 1950s the way was clear for developing biochemical methods to determine alcohol in body fluids.^{60–63} These methods offered milder oxidation conditions and analytical selectivity was enhanced compared with wet-chemistry oxidation procedures. The ADH derived from human or animal liver proved less selective for oxidation of ethanol compared with the enzyme obtained from yeast.⁶² Other aliphatic alcohols (methanol, isopropanol, and *n*-propanol) were oxidized by mammalian ADH but not acetone, which was the most problematic substance for the older wet-chemical methods.⁶⁴ By optimizing the test conditions in terms of pH, reaction time, and temperature, methanol was not oxidized by yeast ADH and this source of the enzyme is still used today for clinical and forensic alcohol analysis.^{62,63}

A typical manual ADH method might entail precipitation of plasma proteins by adding perchloric acid and then adjusting the pH of the supernatant to 9.6 with semicarbazide buffer.⁶² The purpose of the latter reagent, besides adjusting pH, was to trap the acetaldehyde produced during ethanol oxidation and thus drive the reaction to completion. The buffer is usually pre-mixed with the coenzyme NAD^+ before adding to the alcohol-containing supernatant, and finally the ADH enzyme is added to start the reaction. The amount of NAD^+ that becomes reduced to NADH is directly proportional to the concentration of ethanol in the original sample. After allowing the mixture to stand at room temperature for about 1 h to reach an end point, the NADH formed was determined by measuring absorption of ultraviolet (UV) light at a wavelength of 340 nm.

Later developments in ADH methods for analysis of alcohol tended to focus on separation of proteins from the blood by semipermeable membranes (dialysis) or by micro-distillation to obtain an aqueous ethanol solution for analysis.^{65,66} With this modification and a Technicon® AutoAnalyzer device, several hundred blood samples could be analyzed daily.⁶⁵ Scores of publications have appeared describing diverse modifications and improvements to the original ADH method and dedicated “reagent kits” are commercially available. These kits were ideal for use at hospital laboratories and elsewhere where the throughput of samples was relatively low. Otherwise, most efforts were directed toward automating the sample preparation and dispensing reagents to increase sample throughput, and several batch analyzers or reaction rate analyzers appeared including a micro-centrifugal analyzer using fluorescence light scattering for quantitative analysis.^{67,68}

Enzymatic methods for determination of alcohol in body fluids are still used today in part owing to the widespread availability of multichannel analyzers for testing urine for drugs of abuse.⁶⁹ These procedures make use of a technique known as enzyme multiplied immunoassay (EMIT), whereby an enzyme-labeled antigen reacts with ethanol or another drug and the change in color after adding a substrate is measured by spectrophotometry.⁶⁹ The color-intensity is related to the concentration of ethanol in the original specimen. Fluorescence polarization immunoassay (FPIA) and the spin-off technology radiative energy attenuation (REA) are other examples of analytical procedures developed to meet the increasing demand for drugs of abuse testing in urine and therapeutic drug monitoring.^{70–73} In several comparative studies, excellent agreement was found for ethanol determined by REA and by gas chromatography in terms of accuracy and precision.^{70,73} The principles and practice of various immunoassay systems suitable for clinical laboratory analysis were recently reviewed.⁶⁹

Figure 5.2.3 shows a scatter plot comparing ethanol concentrations in urine determined by an automated ADH method and also by headspace gas chromatography. The correlation was excellent: $r = 0.99$. This kind of conventional x - y scatter plot is best redrawn and displayed as a Bland and Altman plot (Figure 5.2.4), whereby the difference in ethanol concentration by the two methods (GC–ADH) is plotted against the average concentration $[(\text{GC} + \text{ADH})/2]$. The mean difference between the two methods indicates whether any bias exists between the two methods, which is a measure of accuracy. The SD of the differences gives the magnitude of scatter or variability of the individual differences and are referred to as limits of agreement between the two methods ($\pm 1.96 \times \text{SD}$), shown as dotted horizontal lines on the plot. This Bland and Altman plot has gained considerable popularity for use in method comparison studies and makes it a lot easier to locate outlier values.⁷⁴ Three such outliers are circled and indicated on the plot; note that these occurred at very high BACs.

Despite many new developments in analytical technology for the analysis of alcohol in body fluids, particularly EMIT, FPIA, and REA methods, gas chromatography still dominates the instrument park at forensic toxicology laboratories owing to its superior selectivity. Indeed, some recent work has shown that elevated concentrations of serum lactate and lactate dehydrogenase might interfere with the analysis of alcohol by ADH methods.^{75–77} This problem was traced to various side reactions whereby the coenzyme NAD^+ was reduced to NADH by endogenous substances and this could not be distinguished from NADH produced during the oxidation of

Figure 5.2.3 Conventional x-y scatter plot showing a high correlation between the concentrations of ethanol in urine determined by an automated enzymatic (ADH) method and by headspace gas chromatography (GC).

Figure 5.2.4 Bland and Altman plot of differences in results between the ADH and GC methods of analysis and the mean result of analysis by the two methods (data from Figure 5.2.3).

ethanol. This resulted in undesirable false positive results when plasma specimens from alcohol-free patients were analyzed.^{76,77}

5.2.3.3 Gas Chromatographic Methods

In the early 1960s, physical-chemical methods began to be used for analysis of alcohol in body fluids such as infrared spectrometry, electrochemical oxidation, and gas-liquid chromatography (GLC).^{78–83} Since then, GLC has become the method of choice for analysis of biological liquids in clinical and forensic laboratories. For determination of ethanol in breath, electrochemistry and infrared methods are widely used.¹⁷ The first GLC methods required that the ethanol was extracted from blood by use of a solvent (e.g., *n*-propyl acetate) or by distillation, which was cumbersome and time-consuming.^{78,79} Later developments meant that the blood was simply diluted (1:5 or 1:10) with an aqueous solution of an internal standard (*n*-propanol or *t*-butanol).^{82,86} The five to ten times dilution with internal standard meant that matrix effects were eliminated and that aqueous alcohol

standards could be used for calibration and standardization of the detector response.⁸² The use of an internal standard also ensured that any unexpected variations in the GLC operating conditions during an analysis influenced the ethanol and the standard alike so the ratio of peak heights or peak areas (ethanol/standard) remained constant.⁸²

The standard procedure entailed injecting 1 to 5 μL of the diluted blood into a heated chamber and any volatiles in the sample were mixed in a stream of helium or nitrogen, the carrier gas or mobile phase, which flowed through a glass or metal column with dimensions such as 2 m long by 0.3 mm inside diameter (i.d.). The column contained the liquid or stationary phase spread as a thin film over an inert solid support material, thus furnishing a large surface area. The volatile components of a mixture were distributed between the moving phase (carrier gas) and the liquid phase and depending on their physicochemical properties such as boiling point, functional groups present, and the relative solubility in the liquid phase, either partial or complete separation occurred during passage through the column. Polar stationary phases were an obvious choice for the analysis of alcohols and polyethylene glycol with average molecular weights of 400, 600, 1500, etc. became widely available and were known as Carbowax phases.⁸³⁻⁸⁶ Otherwise, porous polymer materials such as Poropak Q and S were useful as packing materials for the separating columns when low-molecular-weight, volatile-like alcohols were being analyzed.⁸⁶

A quantitative analysis of ethanol required monitoring the effluent from the column as a function of time originally with a thermal conductivity (TC) detector,⁷⁸ but this was later replaced with a flame ionization detector (FID), which was more sensitive and gave only a very small response to water vapor in body fluids.^{81,82} The ethanol concentration in blood was calculated by comparing the detector response (peak height or peak area) with results of analyzing known strength aqueous alcohol standards and making a calibration plot. Methodological details of many of the older GC methods of blood-alcohol analysis have been reviewed elsewhere.⁸⁴⁻⁸⁶

Figure 5.2.5 is a schematic diagram of the headspace gas chromatographic (GC-HS) analysis, which has become the method of choice in forensic science and toxicology laboratories for determination of ethanol and other volatiles in body fluids.⁸⁷⁻⁹¹ HS-GC requires that the blood samples and aqueous standards are first diluted (1:5 or 1:10) with an aqueous solution of an internal standard and the mixture kept airtight in a small glass vial with crimped-on rubber septum. The vials are then heated to 50 or 60°C for about 30 min to achieve equilibrium between concentrations in gas (C_G) and liquid (C_L) phases for all volatiles in the specimen. Care is needed not to heat the sample for too long at 60°C, otherwise some of the ethanol might be oxidized into acetaldehyde by a non-enzymatic oxidation reaction involving oxyhemoglobin.⁹² This undesirable effect can be avoided by pretreating the blood specimen with sodium azide or sodium dithionite, chemicals that block this oxidation reaction.^{89,92} However, it is simpler to work with a lower equilibrium temperature (40 or 50°C), which also prevents this oxidation reaction.⁸⁹

The headspace vapor can be injected into the gas chromatograph manually with the aid of a gas-tight syringe or, as is more usual, an automated sampling procedure. Automation is preferred because this gives a much more reproducible injection and thus a higher analytical precision. Dedicated equipment for GC headspace analysis has been available since the early 1960s and the U.S. company Perkin-Elmer has dominated the market. Various versions of its headspace instruments have appeared over the years and in chronological order these were called Multifract HS-40, HS-42, and HS-45, the numbers indicating the number of vials in the headspace carousel. A later version was called HS-100, and this was mounted on a Sigma 2000 gas chromatograph allowing automated analysis of up to 100 specimens. The AutoSystem XL GC is the most recent development and works together with TurboMatrix 110 headspace sampler. This arrangement permits overnight batch analysis of up to 110 specimens in a single run.

Packed, wide-bore, and capillary columns are feasible together with headspace gas chromatography and for high resolution work, such as when complex mixtures are being analyzed, capillary columns are essential.^{93,94} Traditional packed columns made of glass or stainless steel are, however, more robust and are still widely used in some laboratories for routine blood-alcohol analysis. Figure

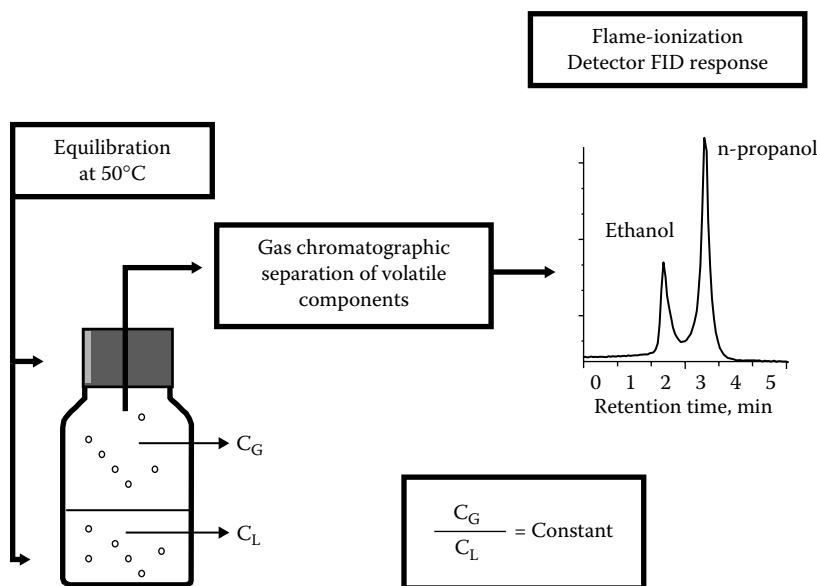

Figure 5.2.5 Schematic diagram of headspace gas chromatography. The blood or urine sample is first diluted 1:10 with an aqueous solution of an internal standard (*n*-propanol) directly into a glass vial made airtight with a crimped-on rubber membrane stopper. After reaching an equilibration at 50°C for 20 to 30 min, a sample of the vapor in equilibrium with the diluted specimen is removed either with a gas-tight syringe or by some automated sampling procedure and injected into the carrier gas (N_2) for transport through the chromatographic column to the detector. The resulting trace (chromatogram) shows a peak for ethanol followed by a peak for the internal standard (*n*-propanol). C_G is the ethanol concentration in the gas or air phase and C_L is the corresponding concentration in the liquid (blood or urine) phase at equilibrium.

5.2.6 gives examples of gas chromatographic traces obtained by headspace analysis of an aqueous mixture of volatiles commonly encountered in forensic toxicology. The column was made of capillary glass designed and marketed especially for blood-alcohol analysis (RtX-BAC1 and RtX-BAC2) and purchased from Restek Corporation (Bellefonte, PA, U.S.A.). The ethanol response is well resolved from potential interfering substances in an isothermal run lasting for 2 min. Table 5.2.5 gives retention times relative to *n*-propanol as internal standard for a wider range of low molecular volatiles under normal HS-GC conditions.

Sampling and analysis of the vapor in equilibrium with the blood specimen has the advantage that non-volatile constituents of the biological matrix (fats, proteins, etc.) do not clog the syringe or the column packing material. Sensitivity of the assay can be enhanced and matrix effects eliminated in another way, namely, by saturating the blood samples and aqueous ethanol standards with an inorganic salt such as NaCl, K_2CO_3 , or Na_2SO_4 , e.g., 0.5 mL blood + 1 g salt.^{86,89} A salting-out technique is useful when trace concentrations of volatiles are analyzed in blood such as endogenous alcohols or alcoholic beverage congeners.^{95–98}

More recently, the headspace vapor in equilibrium with blood or other body fluid can also be removed and transferred to a GC instrument with a solid phase micro-extraction probe.^{99–100} The needle of the probe contains a porous polymer material and this is inserted into the headspace vapor to attain equilibrium with any volatiles in the flask. The probe is then withdrawn from the vial and introduced into the heated injection port of the gas chromatograph. This sampling technique is well suited for analysis of a wide range of volatile agents such as aliphatic and aromatic hydrocarbons as well as many water-soluble alcohols and ketones.⁹⁹

Another modification of the standard headspace analysis involved inclusion of a cryofocusing step prior to GC analysis with a liquid nitrogen freeze trap.¹⁰¹ This serves to concentrate the specimen prior to chromatographic analysis of volatiles with a capillary or wide-bore column. This was the

Figure 5.2.6 Gas chromatographic traces obtained from analysis of an aqueous mixture containing several volatile substances often encountered in forensic blood samples. The analysis was done by headspace gas chromatography using commercially available capillary columns (Restek Corporation) RtX-BAC1 and RtX-BAC2.

Table 5.2.5 Relative Retention Times (min) for Analysis of Volatile Compounds by Headspace Gas Chromatography Using Two Different Stationary Phases

Substance	Stationary Phase RtX-BAC1	Stationary Phase RtX-BAC2
Acetaldehyde	0.53	0.34
Acetone	0.91	0.57
Acetonitrile	0.91	0.81
1-Butanol	2.05	2.20
2-Butanone	1.37	1.04
<i>t</i> -Butanol	0.88	0.69
Ethanol	0.59	0.53
Isopropanol	0.74	0.62
Methanol	0.47	0.40

Note: Times are relative to *n*-propanol as internal standard and all determinations were made with a Perkin-Elmer AutoSystem XL gas chromatograph in isothermal mode and a TurboMatrix 110 headspace sampler.

approach used to measure trace amounts of endogenous volatile alcohols in blood samples or to establish the congener profile in blood after ingesting different kinds of alcoholic beverages.^{97,98,101}

Gas chromatographic methods of analysis have the unique advantage that they combine a qualitative screening analysis of the components of a mixture based on their relative retention time after injection to appearance of the peak with a simultaneous quantitative analysis by measuring the detector response as reflected in the height or area of the resulting peak response.¹⁰² Several comprehensive reviews have dealt with forensic applications of gas chromatography including applications for blood-alcohol analysis.^{14,17,86,103,104} One of these reviews looked at more general

applications of headspace analysis when applied to biological specimens for determination of organic volatile substances, including alcohols.¹⁰⁴

In forensic work, it is advisable to use two different column packing materials, thus furnishing different retention times for ethanol and other volatiles that might be encountered in forensic blood samples. This becomes important whenever blood or tissue samples are putrefied and therefore might contain interfering substances with the same retention times as ethanol on a single stationary phase. The risk of obtaining coincident retention times on two or more stationary phases is reduced considerably. Otherwise, two different methodologies such as GC and chemical oxidation or GC and enzymatic oxidation could be used to analyze duplicate aliquots from the same blood sample.¹⁰⁵ HS-GC with two different detectors (flame ionization and electron capture) has been used to screen biological fluids for a large number of volatiles.¹⁰⁶ Such a dual-detector system was recommended for use in clinical toxicology to aid in the diagnosis of acute poisoning when a host of unknown substances might be responsible for the patient's condition.¹⁰⁷

5.2.3.4 Other Methods

A multitude of other analytical methods exist for blood-alcohol analysis, but none of these can match HS-GC, which is considered the gold standard in forensic and clinical toxicology laboratories. Instead of a flame ionization detector, electrochemical sensing¹⁰⁸ or a metal oxide semiconductor device¹⁰⁹ has been applied to headspace analysis of blood samples. However, lack of a chromatographic separation step meant that neither of these procedures was sufficiently selective when interfering substances might be present. Some authorities recommend making a rapid screening of biological samples by ADH methods to eliminate those that do not contain any alcohol.⁶⁶ All positives are later run by the usual headspace analysis and gas chromatography. This same approach proved suitable for measuring the strength of alcoholic beverages and gave good results compared with a standard gas chromatographic method.¹¹⁰

Several novel methods for alcohol analysis make use of biosensors prepared from immobilized enzymes or bioelectrodes, and these have found applications in clinical chemistry laboratories.^{111–115} The end point of the enzymatic reactions can be monitored either by amperometric, colorimetric, or spectrophotometric methods.^{113,114} The enzyme alcohol oxidase has attracted attention for analysis of alcohol in body fluids and gives reasonably good semiquantitative results.^{115–118} These systems are similar in principle to measuring blood glucose with a glucose oxidase electrode and open the possibility for self-testing applications such as the glucose dipstick technology.

Fourier transform infrared spectrometry (FTIR) was recently applied to the determination of alcohol in beer,¹¹⁹ and when a purge-and-trap capillary GC separation stage was included, FTIR could also be adopted to measure a wide range of low-molecular-weight volatiles including ethanol.¹²⁰ A method based on proton nuclear magnetic resonance spectroscopy proved suitable for use in pharmacokinetic studies to analyze ethanol, acetone, and isopropanol in plasma samples.^{121,122}

In clinical and emergency medicine, depression of freezing point (osmometry) has a long history as a screening test for certain pathological conditions.^{123,124} Diabetes mellitus and uremia are often associated with abnormally high concentrations of plasma-glucose and plasma-urea, respectively. These common conditions cause discrepancies between the osmolality expected from the inorganic ions Na^+ and K^+ and the values measured by depression of the freezing point. Dedicated equipment for osmometry is available at most hospital laboratories and only about 0.2 mL of plasma is needed to measure freezing-point depression. Moreover, the method is nondestructive, which means that the same specimen of plasma can be used later for making a confirmatory toxicological analysis if necessary.¹²⁴

The osmolal gap is defined as the difference between the measured serum osmolality determined by freezing point depression and the calculated serum molarity, from known osmotically active substances in the serum specimen (sodium, potassium urea, glucose, and ethanol).⁴⁰ Indeed, in emergency medicine, ethanol is the commonest cause of finding a high serum osmolality.^{124–126} Ethanol

carries an appreciable osmotic effect because of its low molecular weight (46.05), high solubility in water, and the fact that large quantities are ingested to produce gross intoxication.¹²⁶ Finding a normal osmolal gap speaks against the presence of a high concentration of ethanol but a high osmolal gap does not necessarily rule out that this was caused by ethanol. Other toxic solvents in serum such as acetone, methanol, isopropanol, and ethylene glycol will increase the serum or plasma osmolality as revealed by freezing point depression.¹²⁶ The principal limitation of using osmolal gap as a rapid test for high serum ethanol is the lack of selectivity because other toxic alcohols and non-electrolytes if present will be falsely reported as ethanol. Nevertheless, papers continue to be published dealing with the principles and practice of freezing point osmometry in emergency toxicology.¹²⁷

Considerable interest has developed in point-of-care or near patient testing and in this connection non-invasive methods are preferred. Near-infrared spectrometry is a technique with huge potential for non-invasive analysis of various substances (e.g., tissue glucose) and more recently also tissue ethanol.^{128,129} A light with fixed wavelength is beamed through a subject's fingertip or arm and after processing the absorption bands of the emitted light into their specific wavelengths various constituents in the tissue water can be identified and for some substances a quantitative analysis is possible. However, disentangling the signals of interest from the background noise generated by other biological molecules has proved a challenging problem. Progress is rapidly being made with the aid of sophisticated computer-aided pattern recognition techniques. Near-infrared spectroscopy has already been successfully applied to the analysis of glucose,¹³⁰ and a recent publication described the application of a similar technique for analysis of alcohol in tissue in a completely non-invasive way.¹²⁹ The future of such technology in clinical and forensic work remains to be seen.

The feasibility of combining gas chromatography (GC) to separate the volatile components in a mixture and mass spectrometry (MS) as the detector was demonstrated many years ago.¹³¹ GC-MS provides an unequivocal qualitative analysis of ethanol from its three major mass fragments: m/z 31 (base peak), m/z 45, and m/z 46 (molecular ion).¹³² Isotope-dilution GC-MS is of course feasible if instead of *n*-propanol as internal standard d_5 -ethnaol is used ($C^2H_3^2H_2OH$).¹³³ Selected ion monitoring and deuterium-labeled ethanol was also used to distinguish between ethanol formed post-mortem by the action of bacteria on blood glucose using an animal model.^{134,135} In a clinical pharmacokinetic study, unlabeled ethanol was administered mixed with its deuterium labeled analogue to investigate the bioavailability of ethanol and the role of first-pass metabolism in the gut.¹³⁶

5.2.4 Breath-Alcohol Analysis

The smell of alcohol on the breath of a drinker has always been recognized as a sign of excess alcohol consumption. Quantitative studies demonstrate that only about 1 to 2% of the alcohol ingested is expelled unchanged in the breath. Breath-alcohol instruments were developed to provide a fast and non-invasive way of monitoring alcohol concentration in the blood. A large body of literature has dealt with the principles and practice of breath-alcohol analysis and the associated technology for applications in research, clinical practice, and law enforcement.¹³⁷⁻¹⁴² Analysis of a person's expired air furnishes an indirect way of monitoring volatile endogenous substances in the pulmonary blood and this approach has many interesting applications in clinical and diagnostic medicine.^{143,144} However, the main application of breath-alcohol instruments is in the field of traffic-law enforcement for testing drunk drivers and more recently also for workplace alcohol testing.^{137,141,142} Two categories of instrument for breath-alcohol analysis can be distinguished depending on whether the results are intended as a qualitative screening test for alcohol or as binding evidence for prosecution of drunk drivers (Table 5.2.6).

5.2.4.1 Handheld Screening Instruments

Various handheld devices are available for roadside pre-arrest screening of drinking drivers to indicate whether a certain threshold concentration of alcohol has been surpassed.^{141,142} Such screen-

Table 5.2.6 Classification of Currently Available Instruments for Breath-Alcohol Analysis According to the Main Area of Application and the Analytical Principle Used

Instrument	Main Area of Application	Analytical Principle
Alcolmeter	Roadside screening of motorist, also in the workplace and at hospital casualty departments	Electrochemical oxidation (fuel cell)
Alco-Sensor*	Roadside screening of motorist, also in the workplace and at hospital casualty departments	Electrochemical oxidation (fuel cell)
Alcotest*	Roadside screening of motorist, also in the workplace and at hospital casualty departments	Electrochemical oxidation (fuel cell)
Lifeloc	Roadside screening of motorist, also in the workplace and at hospital casualty departments	Electrochemical oxidation (fuel cell)
Alcotest 7110	Evidence for prosecution of drinking drivers	Electrochemical oxidation and infrared (9.5 μm)
Intoxilyzer 8000	Evidence for prosecution of drinking drivers	Infrared analysis at 3.4 μm and 9.5 μm
BAC Datamaster	Evidence for prosecution of drinking drivers	Infrared analysis at three wavelengths close to 3.4 μm
Intoximeter EC/IR	Evidence for prosecution of drinking drivers	Electrochemical oxidation

* Also being used for roadside evidential testing in some U.S. states.

ing tests are usually conducted at the roadside, and for evidential purposes, a more controlled breath-alcohol analysis is usually mandatory. The instruments for evidential purposes are larger, more sophisticated, and include ways to check accurate calibration, analyze alcohol-free room air, and to produce a printed record of the results. In short, they furnish a quantitative analysis of BrAC and serve as binding evidence for prosecuting drunk drivers.^{145,146} Breath-alcohol instruments have also found applications in clinical pharmacokinetic studies of ethanol and drug-alcohol interactions.^{147,148} Handheld breath-alcohol analyzers are also very practical for use in emergency medicine as a quick and easy way to monitor whether a patient's behavior and signs and symptoms of impairment can be attributed to alcohol influence.^{149–151}

The analytical principles for measuring ethanol in the exhaled air depend in part on the area of application, that is, whether results are intended for qualitative screening or evidential purposes.¹⁴⁸ Most handheld screening devices incorporate electrochemical “fuel-cell” sensors that oxidize ethanol to acetaldehyde and in the process produce free electrons. The electric current generated is directly proportional to the amount of ethanol consumed by the cell (Table 5.2.6). Acetone, which is the most abundant endogenous volatile exhaled in breath, is not oxidized at the electrode surface so elevated concentrations of this ketone (e.g., in untreated diabetes) will not cause a false-positive response.¹⁵² However, if high concentrations of methanol or isopropanol are present in exhaled breath, these also undergo electrochemical oxidation although at different rates compared with ethanol.¹⁵¹ Care is needed when test results with fuel-cell instruments are interpreted because isopropanol, under some circumstances, can be formed in the body by reduction of endogenous acetone.¹⁵³ The concentration of acetone in blood reaches abnormally high levels during food deprivation, prolonged fasting (dieting), or during diabetic ketoacidosis.¹⁵²

5.2.4.2 Evidential Breath-Testing Instruments

Most of the evidential breath-testing instruments used today identify and measure the concentration of alcohol by its absorption of infrared energy at wavelengths of 3.4 or 9.5 μm , which corresponds to the C–H and C–O vibration stretching in the ethanol molecules, respectively (Table 5.2.6).^{17,154–156} Selectivity for identifying ethanol is enhanced by combining infrared absorption at 9.5 μm and electrochemical oxidation within the same unit and the Alcotest 7110 features this dual-sensor technique.^{141,142} Another example from the latest generation of breath-test instruments

Figure 5.2.7 Breath-alcohol profiles during a prolonged exhalation by two test subjects.

is the Intoxilyzer 8000, which makes use of infrared wavelengths at 3.4 and 9.5 μm for identification and analysis of ethanol. This reduces considerably the risk of other breath volatiles, if any exist, being reported as ethanol.

Modern evidential breath-alcohol instruments are equipped with microprocessors that control the entire breath-test sequence including the exhaled volume and alcohol concentration and the exact shape of the BrAC–time profile is monitored and stored in the computer. Examples of exhalation profiles for two individuals tested with a state-of-the-art evidential breath-alcohol analyzer are given in Figure 5.2.7. One notices a rapid rise in the concentration of exhaled ethanol, and after just a few seconds of starting the exhalation, 70% of the final value is reached. Thereafter, the BrAC continues to increase although this occurs much more gradually until the person reaches the end of the exhalation after 9 to 10 s. Note that a BrAC plateau is never reached.

The rules and regulations governing evidential breath-alcohol tests stipulate the need for an observation and deprivation period of at least 15 min before starting the test.^{157–159} Immediately after finishing a drink and for some time afterwards, the concentration of alcohol in the mucous surfaces of the mouth will be higher than that expected from the coexisting BAC. Time is needed for the alcohol to dissipate, and many studies have shown that this takes 15 to 20 min even after gargling with whisky or mouthwash.^{160,161} The latest generation of breath-alcohol analyzers is equipped with algorithms that monitor the shape of the BrAC exhalation profile to help disclose abnormalities that might be caused by mouth alcohol. Besides the problem with alcohol in the mouth from a recent drink, the operator of the breath instrument should also ensure the person does not hiccup, burp, belch, or regurgitate stomach contents just before testing. This might result in a more dangerous form of mouth alcohol that is not so easily detected by monitoring the slope of the exhalation profile.¹⁶²

Reporting results of breath-alcohol analysis can be a bit confusing and depends on whether the testing was done for clinical or traffic law enforcement purposes. In hospitals, it is standard practice

Figure 5.2.8 Relationship between the concentrations of ethanol in venous blood and end-expired breath determined with Intoxilyzer 5000, a quantitative infrared analyzer.

to translate the measured BrAC into the presumed concentration in venous blood, which requires use of a calibration factor. This is referred to as the blood/breath ratio and the instrument gives results directly in terms of BAC derived as $[\text{BrAC} \times \text{ratio} = \text{BAC}]$. The value of the blood/breath ratio is generally taken to be 2100:1 (U.S. and Canada) although values of 2300:1 (U.K., Ireland, and Holland) and 2000:1 (Germany, France, Spain) are accepted. For legal purposes the BrAC is not converted to BAC but instead as g/210 L breath in U.S. so the 2100:1 blood/breath ratio is affirmed by statute.^{159,160} However, many blood-alcohol and breath-alcohol comparisons show that a factor of 2100:1 gives a generous margin of safety to the individual.

Direct comparisons have shown that the concentration of alcohol in venous blood is about 10 to 15% higher compared with BrAC ($\times 2100$) when samples are taken in the post-absorptive phase.¹⁵³ A closer agreement between the two methods of measurement is obtained using a 2300:1 factor for calibration purposes.¹⁵⁴ This is illustrated in Figure 5.2.8, which compares mean concentration-time profiles in venous blood and end-exhaled breath in ten subjects after they drank 0.4 g ethanol per kg body weight at about 2 h after their last meal.¹⁵⁶ The breath-alcohol instrument in this study was an Intoxilyzer 5000, which has been widely used for legal purposes in the U.S. and elsewhere.^{153,155,163}

5.2.4.3 Blood/Breath Ratio of Alcohol

Studies have shown that the BAC/BrAC ratio of alcohol changes as a function of the time after drinking depending on whether tests were made on the absorption or the post-absorptive part of the alcohol curve.^{164–166} The blood-to-breath alcohol ratio tends to be less than 2100:1 (1800 to 2000) during the absorption phase and greater than 2100:1 (2200 to 2400) in the post-absorptive phase. One reason for this temporal variation stems from the fact that venous instead of arterial blood was used for determination of alcohol.^{167,168} The alcohol concentration in pulmonary blood reaching the air sacs (alveoli) of the lungs runs closer to the concentration in arterial blood transporting alcohol to tissue water compared with venous blood returning blood to the heart.

Figure 5.2.9 shows mean concentration–time profiles of alcohol derived from blood samples drawn from indwelling catheters in a radial artery at the wrist and a cubital vein at the elbow on the same arm.¹⁶⁷ The volunteers were healthy men who drank a moderate bolus dose of ethanol (0.6 g/kg body weight) 5 to 15 min before providing specimens of venous and arterial blood nearly simultaneously at various times after drinking ended. The concentration of alcohol in arterial blood samples exceeded venous blood samples during the first 90 min post-dosing whereas at all later

Figure 5.2.9 Mean blood-alcohol curves comparing the concentrations of ethanol in blood from a radial artery and a cubital vein on the same arm. The curves depict nine healthy men who drank 0.6 g ethanol per kg body weight in 2 to 15 min. Standard error bars are omitted for clarity.

times the venous blood was slightly higher than arterial blood. The arterial and venous concentrations were the same at only one time point at about 90 min post-drinking.

Note that for clinical applications, the breath-alcohol instruments are calibrated to estimate the alcohol concentration in whole blood and not the concentration in plasma or serum. This is often overlooked by clinicians who fail to appreciate the difference between whole blood and plasma concentrations of alcohol. To derive the concentration of alcohol in plasma or serum indirectly by analysis of breath, the instrument would need to be calibrated with a plasma/breath factor of about 2600:1 because whole blood contains about 15% less alcohol than the same volume of plasma or serum (Table 5.2.3).

When breath-alcohol testing is used for traffic law enforcement the results are almost always reported as the concentration of alcohol in the breath analyzed without considering the person's BAC. This avoids making any assumptions about the blood/breath ratio and its variability between and within individuals. Statutory limits for driving in many countries are therefore written in terms of threshold BAC and BrAC depending on the specimen analyzed.¹⁶⁶ Evidential breath-alcohol tests should be done in duplicate and the protocol should include analysis of room air blank and a known strength air-alcohol mixture as a control standard.^{169,170} Results from all breath and control tests along with the date and time of testing as well as positive identification of the suspect should be available as a print-out and also stored online for later downloading to a central computer network.^{169,170}

5.2.5 Quality Assurance Aspects of Alcohol Analysis

Much has been written about quality assurance of clinical laboratory analysis including concepts such as precision, accuracy, linearity, recovery, sensitivity, and limits of detection and quantitation of the method.¹⁷¹ In addition, when results are used as evidence in criminal and civil litigation, the chain of custody record of the specimens is extremely important to document. This chain must be maintained intact from the moment of sampling to the moment results are reported, and each person involved in handling, transport, analysis, and storage of the specimen must be traceable from the written records. The entire analytical procedure including the actual chromatographic traces as well as proof that the instrument was properly calibrated on the day the blood specimens were analyzed might need to be verified at a later date. Participation in nationally or internationally recognized external proficiency tests is another essential element of quality assurance of laboratory results.¹⁷²

The important concepts in development and validation of analytical methods include accuracy, precision, linearity, range, specificity/selectivity, limit of detection, and quantitation, and these terms are explained in brief below.^{170,171}

Accuracy is defined as the closeness of agreement of the analytical result with a known reference or assigned value. Accuracy is therefore a measure of the exactness of the method. The difference if any between the true value and the value found is called analytical bias.

Precision describes the magnitude of random error as reflected in the closeness of agreement of multiple determinations on the same specimen. If the replicate measurements are made within the same analytical run, the calculated precision estimated is referred to as repeatability of the method. When replicates are made in different runs or at different laboratories by different people, then the analytical precision is referred to as reproducibility of the method. In mathematical terms, precision is reflected in the standard deviation (SD) of at least ten replicate measurements at a certain concentration of the target analyte. For obvious reasons, reproducibility can be expected to be poorer than repeatability. For blood-ethanol assay, the SD tends to increase as concentration in the specimen increases, and therefore precision is often expressed as a coefficient of variation $(SD/mean) \times 100$, which tends to decrease slightly as the concentration of ethanol increases.

The terms **sensitivity** and **specificity** are often used interchangeably and they generally refer to a method's ability to distinguish between different analytes in a mixture and allow a response for just the substance of interest, that is, without interference from potential endogenous or exogenous compounds.

Linearity is the ability of a method to give results that are directly proportional to concentration of the target analyte or can be expressed by a well-defined mathematical transformation and shown to be a function of concentration over a certain range.

The **range** is the interval between the upper and lower concentrations of analyte that can be determined with sufficient accuracy, precision, and linearity.

The **limit of detection** (LOD) is the lowest concentration of analyte in a specimen that can be distinguished from background signals or instrument noise. Mathematically LOD is defined as $3 \times$ the SD obtained from analysis of a blank specimen.

The **limit of quantitation** (LOQ) is the concentration of analyte in a sample that can be determined with certainty. Mathematically LOD is defined as $10 \times$ the SD obtained from analysis of a blank specimen.

The most important features of pre-analytical, analytical, and post-analytical aspects of blood-alcohol analysis are presented below.

5.2.5.1 Pre-Analytical Factors

The subject or patient should be informed of the reason for taking a blood sample and, when necessary, informed written consent obtained. The equipment used for drawing blood is normally an evacuated tube (5- or 10-mL Vacutainer tubes) with sterile needle attachment. The blood is taken from an antecubital vein, and if necessary a tourniquet is applied to make it easier to visualize a suitable vein. The volume of blood drawn depends on the requirements and number of substances to be analyzed whether only ethanol or ethanol and other drugs of abuse. Even though in the case of ethanol only a few hundred microliters of blood are needed for each assay, the Vacutainer tubes should be filled with as much blood as possible. Sufficient blood should be available to allow making several determinations of the ethanol concentration and any retesting that might be necessary as well as common drugs of abuse. The specimen tubes should be gently inverted a few times immediately after collection to facilitate mixing and dissolution of the chemical preservatives; sodium fluoride (10 mg/mL) to inhibit the activity of various enzymes, microorganisms, and yeasts, and potassium oxalate (5 mg/mL) as an anticoagulant. The tubes of blood should be labeled with the person's name, the date and time of sampling, and the name of the person who took the sample should also be recorded. The Vacutainer tubes containing blood should be sealed in such a way as

to prevent unauthorized handling or tampering and special adhesive paper strips are available for this purpose. The blood samples and other relevant paperwork should then be secured with tape so that any deliberate manipulating or adulteration is easily detected by laboratory personnel after shipment. After taking the samples, the tubes of blood should be stored in a cold room before being sent to the laboratory by express courier mail service.

The question of a deficient blood volume in the Vacutainer tubes sent for analysis of alcohol and the influence this might have on accuracy of HS-GC analysis was recently investigated in two separate publications.^{173,174} It was alleged that a very small volume of blood meant an excess amount of sodium fluoride and that this increased the ethanol concentration in the headspace flask by a salting-out effect. This led to an acquittal in a drunken driving case trial in the court of appeals in the U.K., and the prosecution failed to rebut the argument with expert testimony. The new studies showed that an abnormally high concentration of NaF increased not only the concentration of ethanol in the headspace but also the concentration of the *n*-propanol internal standard. Because the ratio of responses EtOH/PrOH is used for quantitative analysis, the resulting ethanol concentration should be unchanged. In reality, it was shown that *n*-propanol was salted-out slightly more effectively than ethanol with the net result that the blood-ethanol concentration reported was lower than expected and was thus to the suspect's benefit.

Although pre-analytical factors are probably more important to consider when endogenous substances are analyzed such as in clinical chemistry laboratories, a standardized sampling protocol is also important for forensic blood-alcohol analysis.^{175,176} Two tubes of blood should be drawn in rapid succession and the skin cleaned with soap and water and not with an organic solvent such as ether, isopropanol, or ethanol. Obviously, the blood samples should not be taken from veins into which intravenous fluids are being administered.¹⁷⁷ This kind of emergency treatment is often given as a first-aid to counteract shock or trauma as a result of involvement in traffic accidents. The blood samples should be taken only by trained personnel such as a phlebotomist, registered nurse, or physician.

5.2.5.2 Analytical Factors

The blood specimens must be carefully inspected when they arrive at the laboratory making a note whether or not the seals on the package as well as the individual tubes of blood are intact. If the specimen seems unusually dilute or if there are blood clots, then this should be noted. There are two ways to deal with clotted samples: (1) either centrifuge the specimen and use an aliquot of the supernatant for analysis and then report the results as a serum concentration or (2) homogenize the clot and analyze an aliquot of the hemolyzed blood specimen. Details of any mishaps occurring during transport of specimens such as breakage of the packaging, leakage of blood, etc., as well as the date and time of arrival should be recorded. Information written on the Vacutainer tubes should be compared with other documentation to ensure the suspect's name and the date and time of sampling are correct. The same unique identification number or barcode should be added to all paperwork and biological specimens received and this number used to monitor passage of the specimens through the laboratory. Ensure that the erythrocytes and plasma fractions are adequately mixed before removing aliquots of whole blood for analysis of ethanol. Replicate determinations can be made with different chromatographic systems and preferably by different technicians working independently. Any unidentified peaks on the gas chromatograms should be noted because these might indicate the presence of other volatiles in the blood sample.

5.2.5.3 Post-Analytical Factors

Quality assurance of individual results can be controlled by looking at critical differences (range) between replicate determinations.¹⁷⁰ The size of the difference will be larger, the higher the con-

centration of ethanol in the blood specimen because precision tends to decrease with an increase in the concentration of ethanol. Control charts offer a useful way to monitor day-to-day performance in the laboratory; one chart is used to depict random errors or precision and another chart to show systematic errors or bias derived by analysis of known strength standards together with unknowns.^{178,179} These charts make it easy to detect sudden deterioration in analytical performance as shown by the scatter of individual values and the number of outliers.¹⁷⁸

The rate of loss of alcohol during storage needs to be established under refrigerated conditions (+4°C) and also when specimens are kept deep frozen.^{180–182} If necessary, corrections can be applied to blood specimen reanalyzed after prolonged periods of storage. In our experience, the blood-ethanol concentration decreases only slightly during storage at 4°C at a rate of 1 to 2 mg/dL per month.¹⁴⁸ Chromatographic traces and other evidence corroborating the analytical results such as calibration plots or response factors all need to be carefully labeled and stored in fire-proof cabinets. Today it is virtually mandatory that a forensic science or toxicology laboratory be accredited for the tasks they perform.^{183,184} Participation in external proficiency trials of analytical performance is also a mandatory requirement to build confidence in the analytical reports.^{172,185} When analytical results are used for criminal prosecution, information of the kind discussed above must be open to discovery and needs to be available for scrutiny.

5.2.5.4 Interlaboratory Proficiency Tests

Two papers looked at the results from interlaboratory proficiency tests of blood-alcohol analysis at clinical chemistry laboratories.^{172,185} In one study, originating from Sweden, all participants were clinical chemistry laboratories and all used gas chromatographic analysis of plasma-ethanol. The coefficients of variation (CVs) between laboratories were within the range 10 to 17%.¹⁷² In a similar study among U.K. laboratories, the corresponding CVs depended in part on the kind of methodology used for determination alcohol and immunoassays generally performed worse than gas chromatographic methods (liquid injection and headspace technique) and the CVs ranged from 8 to 20%.¹⁸⁵ It should be noted that determination of toxicological substances such as ethanol in blood is not the primary concern of clinical chemistry laboratories.

Table 5.2.7 presents results from an interlaboratory comparison of blood-alcohol analysis at specialist forensic toxicology laboratories in the Nordic countries (Denmark, Finland, Iceland, Norway, and Sweden). All participants used headspace gas chromatography for the determinations and the blood samples were obtained from apprehended drinking drivers. The CV between labo-

Table 5.2.7 Results of a Declared Interlaboratory Proficiency Test of Blood-Alcohol Analysis at Specialist Forensic Toxicology Laboratories in the Nordic Countries

Laboratory	Blood-1	Blood-2	Blood-3	Blood-4	Blood-5	Blood-6
1	0.46	1.01	2.15	1.62	0.74	1.75
2	0.47	1.01	2.27	1.70	0.78	1.83
3	0.46	1.01	2.26	1.67	0.77	1.81
4	0.47	1.00	2.17	1.66	0.78	1.81
5	0.48	1.01	2.15	1.66	0.78	1.79
Mean	0.47	1.01	2.20	1.66	0.77	1.80
SD	0.008	0.005	0.060	0.029	0.017	0.030
CV%	1.7%	0.49%	2.7%	1.7%	2.2%	1.7%

Notes: Venous blood samples were taken from apprehended drinking drivers in sterile tubes containing sodium fluoride and potassium oxalate as preservatives. The blood was portioned out into other tubes and sent to participating laboratories as a declared proficiency trial. As seen, the CVs between-laboratories were always less than 3% and the corresponding within-laboratory CVs were mostly less than 1% (data not shown).

ratories was always less than 3% regardless of the concentration of alcohol present, which testifies to highly reproducible analytical work. The corresponding CVs within laboratories were mostly 1% or less based on three to six determinations per sample. If the overall mean BAC in each sample is taken as the target value, then all laboratories showed accuracy to within $\pm 5\%$ of the attributed concentration.

5.2.6 Fate of Alcohol in the Body

Ethanol is a small polar molecule with a low molecular weight (46.07) and carries weak charge (see Table 5.2.2), which facilitates easy passage through biological membranes.^{186,187} After ingestion, absorption of ethanol starts already in the stomach but this process occurs much faster from the upper part of the small intestine where the available surface area is much larger owing to the presence of microscopic villi covering the mucosal cells. Both the rate and extent of absorption is delayed if there is food in the stomach before drinking.^{188,189} The blood that drains the gastrointestinal tract leads to the portal vein where any alcohol present must pass through the liver, and then via the hepatic vein on to the heart and the systemic circulation. After passage through the liver, ethanol distributes uniformly throughout all body fluids and tissue without binding to plasma proteins. Indeed, it is possible to determine total body water by the ethanol dilution method.¹⁸⁷

The peak BAC reached after drinking (C_{\max}) and the time required to reach the peak (t_{\max}) vary widely from person to person and depend on many factors.¹⁸⁷ After 48 healthy male volunteers drank 0.68 g ethanol/kg body weight as neat whisky on an empty stomach, the peak concentration in capillary (fingertip) blood was reached at exactly 10, 40, 70, and 100 min after the end of drinking for 23, 14, 8, and 3 subjects, respectively.¹⁹⁰ The amount of alcohol consumed, the rate of drinking, the dosage form (beer, wine, spirits, cocktails), and most importantly the rate of gastric emptying will influence the speed of ethanol absorption.¹⁸⁷ The concentrations of ethanol in body fluids and tissues after reaching equilibration depend primarily on the water contents of these fluids and tissues and the ratio of blood flow to tissue mass.¹⁸⁷ Figure 5.2.10 shows the mean concentration–time profiles of ethanol in blood, breath, urine, and saliva obtained in experiments with healthy male volunteers who drank 0.68 g/kg as neat whisky in 20 min after an overnight fast.^{187,191} Note that the concentrations in breath have been multiplied by an assumed average blood/breath ratio of 2100:1.

Figure 5.2.10 Mean concentration–time profiles of ethanol in venous blood, end-expired breath ($\times 2100$), saliva, and urine from experiments with healthy men who ingested 0.68 g ethanol per kg body weight as neat whisky in the morning after an overnight fast. Standard error bars are omitted for clarity.

The bulk of the dose of alcohol (95 to 98%) is eliminated by oxidative metabolism, which occurs via enzymatic reactions in the liver catalyzed by class I enzymes of alcohol dehydrogenase (ADH).^{186,187} Between 2 and 5% of the dose is excreted unchanged in breath, urine, and sweat and a very small fraction (~0.1%) is conjugated with glucuronic acid and removed via the kidney.¹⁹² Small amounts of alcohol are thought to undergo pre-systemic oxidation in the gastric mucosa or the liver or both organs but the practical significance of first-pass metabolism (FPM) is dose dependent and is not easy to quantify.¹⁹³

At moderate BAC (>60 mg/dL), the microsomal enzymes (P4502E1), which have a higher k_m for oxidation of ethanol (60 to 80 mg/dL) compared with ADH ($k_m = 2$ to 5 mg/dL), become engaged in the metabolism of ethanol.^{194–196} The P450 enzymes are also involved in the metabolism of many drugs and environmental chemicals, which raises the potential for drug–alcohol interactions, which might explain the toxicity of ethanol in heavy drinkers and alcoholics.^{197–202} Moreover, the activity of P4502E1 enzymes increases after a period of continuous heavy drinking owing to a faster *de novo* synthesis of the enzyme and metabolic tolerance develops as reflected in twofold to threefold faster rates of elimination of alcohol from the bloodstream in alcoholics undergoing detoxification.^{200–204}

The detrimental effects of ethanol on performance and behavior are complex and involve interaction with the membrane receptors in the brain associated with the inhibitory neurotransmitters glutamate and gamma aminobutyric acid (GABA).^{205–208} The behavioral effects of ethanol are dose-dependent and after drinking small amounts the individual relaxes, experiences mild euphoria, and becomes more talkative. As drinking continues and the blood-ethanol concentration increases toward 150 to 200 mg/dL, impairment of body functioning becomes pronounced. Many of the pharmacological effects of ethanol can be explained by an altered flux of ions through the chloride channel activated by the neurotransmitter GABA.²⁰⁶ The link between ethanol impairment and neurotransmission at the GABA_A receptor also helps to explain observations about cross-tolerance with other classes of depressant drugs like benzodiazepines and barbiturates, which also bind to the GABA_A receptor complex to open a chloride ion-channel to alter brain functioning.²⁰⁰

Although there is a reasonably good correlation between degree of ethanol-induced impairment and the person's BAC, there are large variations in response at the same BAC in different individuals who drink the same amount of alcohol within the same time frame. The reasons for this are twofold; first, larger people tend to have more body water so the same dose of alcohol enters a larger volume resulting in lower BAC compared with lighter people with less body water. This phenomenon is known as consumption tolerance and stems from variations in body weight and the relative amount of adipose tissue, which is influenced by age, gender, and ethnicity.^{209,210} The second reason for interindividual differences in ethanol-induced performance decrement is called concentration tolerance, which is linked to a gradual habituation of brain cells to the presence of alcohol during repeated exposure to the drug.^{210,211} Besides the development of acute tolerance (Mellanby effect), which appears during a single exposure (see Chapter 5.1), a chronic tolerance develops after a period of continuous heavy drinking. Among the mechanisms accounting for chronic tolerance are long-term changes in the composition of cell membranes particularly, the cholesterol content, the structure of the fatty acids, and also the arrangement of proteins and phospholipids making up the lipid bilayer.^{210,211}

In occasional drinkers, the impairment effects of ethanol appear gradually, becoming more exaggerated as BAC increases. The various clinical signs and symptoms of intoxication are usually classified as a function of BAC from sober to dead drunk as was first proposed by Bogen.²¹² This scheme has subsequently been developed further and improved upon by others. For example, at a BAC of 10 to 30 mg/dL alterations in a person's performance and behavior are insignificant and can only be discerned using highly specialized tests such as divided attention tasks. Between 30 and 60 mg/dL, most people experience euphoria, becoming more talkative and sociable owing to disinhibition. At a BAC between 60 and 100 mg/dL euphoria is more marked, often causing excitement with partial or complete loss of inhibitions and in some individuals judgment and control are seriously impaired. When the BAC is between 100 and 150 mg/dL, which are concentrations

seldom reached during moderate social drinking, psychomotor performance deteriorates markedly and poor articulation and speech impediment is obvious. Between 150 and 200 mg/dL ataxia is pronounced and drowsiness and confusion are evident in most people. The relationship between BAC and clinical impairment is well documented in drunk drivers who often reach very high BACs of 350 mg/dL or more, but most of these individuals are obviously chronic alcoholics.^{213,214} In two recent studies of forensic autopsies, the average BAC when death was attributed to acute alcohol poisoning was 360 mg/dL.^{215,216}

It is important to note that the impairment effects of alcohol depend to a great extent on the dose and the speed of drinking and whether the person starts from zero BAC or not.^{217,218} The person's age and experience with alcohol are important owing to the development of central nervous system tolerance.²¹⁹ People who are capable of functioning with a very high BAC, such as drunk drivers, e.g., 200 to 300 mg/dL, have probably been drinking continuously for several days or even weeks so that a chronic tolerance to alcohol has had time to develop. Drinking a large volume of neat spirits in a short time results in nausea, gross behavioral impairment, and marked drunkenness, and an inexperienced drinker runs the risk of losing consciousness and suffering acute alcohol poisoning. Drinking too much too fast is dangerous, and if gastric emptying is rapid, the BAC rises with such a velocity that a vomit reflex in the brain is triggered. This physiological response to acute alcohol ingestion has probably saved many lives.

Conducting controlled studies with people who drink to reach very high BAC are difficult to motivate for ethical reasons. One exceptional study was reported by Zink and Reinhardt,²²⁰ who allowed healthy male volunteers to consume very large quantities of alcohol, either as beer or spirits or both, continuously for 8 to 10 h under social conditions. The BAC profiles were established unequivocally by frequent blood sampling from indwelling catheters every 15 to 20 min for up to 10 h. Some of the subjects reached abnormally high BAC of over 3.0 g/kg (300 mg/dL) and all developed a high degree of tolerance to the effects of alcohol. Figure 5.2.11 gives examples of the blood-concentration time profiles for four of the men who participated in this German study. Note that BAC is given in mass/mass (g/kg) as is customary in Germany and not weight/volume.

5.2.7 Clinical Pharmacokinetics of Ethanol

Clinical pharmacokinetics deals with the way that drugs and their metabolites are absorbed, distributed, and metabolized in the body and how these processes can be described in quantitative terms.^{221–224}

5.2.7.1 Widmark Model

The clinical pharmacokinetics of ethanol has been investigated extensively since the 1930s thanks to the early availability of a reliable method of analysis in small volumes of blood.²⁰⁹ Figure 5.2.12 shows a typical BAC–time profile after a healthy male subject drank 0.68 g/kg ethanol as neat whisky in the morning on an empty stomach. Before any pharmacokinetic evaluation of this curve is attempted, the data points on the post-absorptive phase should be carefully inspected and shown to fit well on a straight line. One indication of this is a high correlation coefficient ($r > 0.98$) for the concentration–time data points. The rectilinear declining phase is then extrapolated back to the ordinate (y-axis) or the time of starting to drink to give the C_0 parameter. This represents the concentration of ethanol in blood if the entire dose was absorbed and distributed in all body fluids and tissues without any metabolism occurring. The ratio of dose (g/kg) to C_0 (g/L) gives the ratio of body alcohol concentration to BAC and is known as the apparent volume of distribution, denoted “ r ” by Widmark or more recently V_d in units of L/kg. Inspection of this parameter allows a check on the validity of the experiment and the kinetic analysis because V_d can only take certain values. The value expected corresponds to the ratio of water in the whole body (60%) to the water content

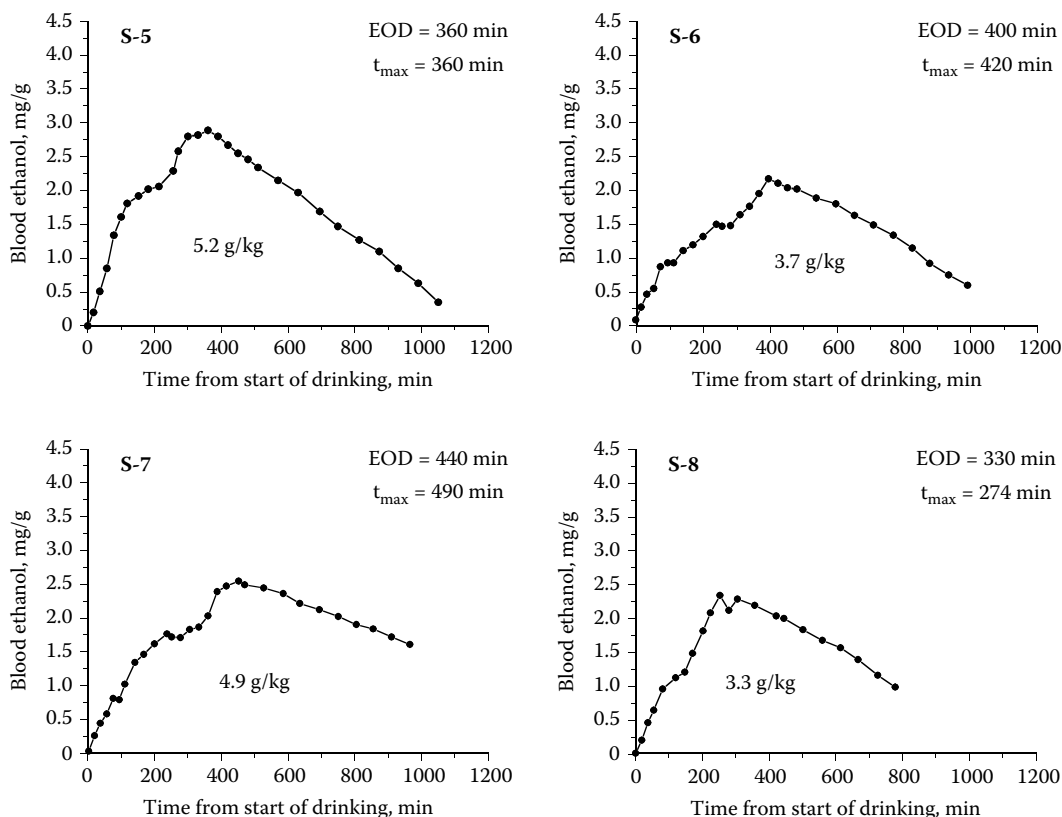

Figure 5.2.11 Concentration–time profiles of ethanol in four subjects (S-5 to S-8) who consumed very large quantities of alcohol (3.3 to 5.2 g/kg body weight) during a drinking time of 8 to 10 hours under controlled social conditions. EOD is time to end of drinking and t_{\max} is time to reach the maximum BAC. Curves are redrawn from information published by Zink and Reinhardt.²²⁰

Figure 5.2.12 Blood-alcohol profile typically obtained after ingestion of a moderate dose of alcohol (0.68 g/kg) as neat whisky in 20 min after an overnight fast. Key pharmacokinetic parameters and how these are calculated are shown on the graph (see text for details).

Figure 5.2.13 Concentration–time profile of ethanol in venous blood after one subject received 0.8 g ethanol per kg body weight by constant rate intravenous infusion over 40 min. The pharmacokinetic parameters are defined on this graph (see text for details).

of the blood (80%) and thus a ratio of 0.6 to 0.7 L/kg for a healthy male and 0.5 to 0.6 L/kg for a female.²⁰⁹

Alcohol can also be administered intravenously, which is sometimes desirable in research and clinical investigations to avoid problems with variable gastric emptying and to avoid first-pass metabolism occurring in the stomach or the liver or both organs.²²⁴ In the example shown in Figure 5.2.13, the test subject received 0.80 g/kg as a 10% w/v solution in saline at a constant rate for 40 min. The peak BAC now coincides with the end of the infusion period and this is followed by a diffusion plunge, during which time ethanol equilibrates between the well-perfused central blood compartment and poorly perfused resting skeletal muscle tissues. At about 90 min post-infusion, the BAC starts to decrease at a constant rate per unit time in accordance with zero-order kinetics and the slope of this rectilinear disappearance phase is commonly referred to as the alcohol burn-off rate or β -slope. However, specialist textbooks in pharmacokinetics refer to the zero-order elimination slope as k_0 instead of β .²²⁴ When the blood concentration decreases below about 10 mg/dL or after about 450 min post-dosing in Figure 5.2.13, the linear declining phase becomes curvilinear for the remainder of time alcohol is still measurable in the blood.^{223,224} The elimination of alcohol now follows first-order kinetics and the rate constant is denoted k_1 . Some studies showed that the half-life of this terminal phase was about 15 min.²²⁵

The first person to make a comprehensive mathematical analysis of BAC profiles was Erik M.P. Widmark and details of his life and work have been published.²²⁶ Widmark introduced the following equation to represent the elimination kinetics of alcohol from blood in the post-absorptive phase.

$$C_t = C_0 - \beta t \quad (1)$$

where C_t = blood alcohol concentration at some time t on the post-absorptive part of the curve, C_0 = blood alcohol concentration extrapolated to the time of starting to drink, β = rate of elimination of alcohol from blood, and t = time in minutes.

The rate of elimination of alcohol from the blood in moderate drinkers falls within the range 10 to 20 mg/dL/h with a mean value of about 15 mg/dL/h.^{197,209,225} Higher values are seen in drinking drivers (mean 19 mg/dL/h)²²⁷ and in alcoholics undergoing detoxification (mean 22 mg/dL/h).^{228–231}

The faster burn-off rates seen in heavy drinkers is probably one consequence of enzyme induction, which boosts the activity of the microsomal P4502E1 system during prolonged exposure to high concentrations of ethanol.^{196,230,232} The P4502E1 enzymes have a higher K_m (60 to 80 mg/dL) compared with ADH (2 to 5 mg/dL) and the slope of the elimination phase tends to be steeper when starting from a higher initial BAC, such as in alcoholics compared with moderate social drinkers.²³⁰ In a controlled study with alcoholics undergoing detoxification, the mean β -slope was 22 mg/dL/h with a range from 13 to 36 mg/dL/h.²²⁸ Liver disorders such as alcoholic hepatitis and cirrhosis did not seem to influence the rate of disposal of alcohol in these individuals.²²⁸ When recently drinking alcoholics with high rates of alcohol elimination from blood were allowed to sober up for a few days and dosed again with a moderate amount of alcohol, the elimination rate was now in the range expected for moderate drinkers, namely, 15 mg/dL/h.²³⁰

The rate of elimination of alcohol from the blood was not much influenced by the time of day when 0.75 g/kg was administered at 9 A.M., 3 P.M., 9 P.M., and 3 A.M., according to an investigation into chrono-pharmacokinetics of ethanol.²³³ However, gastric emptying seems to occur faster in the morning as reflected in a 32% higher peak BAC and an earlier time of its occurrence when ethanol (1.1 g/kg body weight) was consumed between 7.15 and 7.45 A.M., compared with the same time in the evening.²³⁴ Smoking cigarettes slows gastric emptying and as a consequence delays the absorption of a moderate dose (0.50 g/kg) of ethanol resulting in a lower peak BAC in smokers.²³⁵

By extrapolating the rectilinear elimination phase back to the time of starting to drink, one obtains the y -intercept (C_0), which corresponds to the theoretical BAC expected if the entire dose was absorbed and distributed without any metabolism occurring (Figure 5.2.13). The empirically determined value of C_0 will always be greater than the ratio of dose/body weight because whole blood is 80% w/w water compared with the body, which is 60% w/w on average for men and 50% for women. The apparent volume of distribution (V_d) of alcohol is given by the ratio of dose (g/kg) divided by C_0 and in clinical pharmacology textbooks this is referred to as V_d with units of L/kg.^{221–223} However, because BAC in Widmark's studies was reported in units of mg/g or g/kg, dividing the dose by C_0 gives a ratio without any dimensions. This needs to be considered whenever BAC is reported as weight/volume units (e.g., g/L) as is more usual today. The density of whole blood is 1.055 g/mL, which means there is an expected difference of 5.5% compared with values of V_d reported by Widmark.²⁰⁹

Values of the distribution factor " r " differ between individuals depending on age and body composition particularly the proportion of fat to lean body mass.²³⁶ Obviously, the value of " r " will also depend on whether whole blood or plasma specimens were analyzed and used to plot the concentration–time profile when back-extrapolation is done to determine C_0 . As shown in Figure 5.2.2, the plasma–alcohol curves run on a higher level compared with whole blood–alcohol curves because of the differences in water content as discussed earlier. This means that C_0 is higher for plasma curves compared with whole-blood curves.⁴⁷

According to Widmark's second equation, the relationship between alcohol in the body and alcohol in the blood at equilibrium can be represented by the following equations:

$$A/(p \times r) = C_0 \quad (2)$$

$$A = C_0 \times (p \times r) \quad (3)$$

where A = amount of alcohol in grams absorbed and distributed in all body fluids, p = body weight of the person in kg, r = Widmark's " r " factor, and C_0 = y -intercept (Figure 5.2.13).

These equations make it is easy to calculate the amount of alcohol in the body from the concentration determined in a sample of blood provided that the value of " r " is known and that absorption and distribution of ethanol were complete at the time of sampling blood. However, in reality 100% absorption of the dose is only achieved when ethanol is given by intravenous infusion. Thus, the above equation will tend to overestimate the person's true BAC because part of an orally

administered dose might be cleared by first-pass metabolism occurring either in the stomach or liver or in both places. Although the above equation has been much used in forensic alcohol calculations, it should not be applied to other drugs and narcotics and especially not in post-mortem toxicology, owing to problems with variation in drug concentrations in different sampling sites (see Section 5.2.3).

In the fasting state, the factor “ r ” will depend on age, gender, and body composition and Widmark reported mean values of 0.68 for 20 men (range 0.51 to 0.85) and 0.55 for 10 women (range 0.49 to 0.76).²⁰⁹ However, in many later studies, which included more volunteer subjects, it was found that average values of “ r ” were closer to 0.70 L/kg for men and 0.60 L/kg for women with 95% confidence limits of about $\pm 20\%$.²³⁷

The two separate Widmark equations for β and “ r ” can be easily combined by eliminating C_0 to give the following equation:

$$A = pr(C_t + \beta t) \quad (4)$$

The above equation is useful to estimate the total amount of alcohol absorbed from the gastrointestinal tract since the beginning of drinking or by rearrangement, the BAC (C_t) expected after intake of a known amount of alcohol.

$$C_t = (A/pr) - \beta t \quad (5)$$

When calculating BAC from the dose administered, or vice versa, it is necessary to assume that systemic availability is 100% and that absorption and distribution of alcohol into total body water is complete at the time of sampling blood. Furthermore, individual variations in β and “ r ” introduce uncertainty in the calculated dose (A) or BAC (C_t) when average values are applied to random subjects from the population. Various modifications or improvements have been suggested, such as by using estimates of total body water, lean body mass, or nomograms based on body mass index.^{236–238} The individual variation has been estimated to $\pm 20\%$ for 95% confidence limits in tests involving more than 100 subjects who drank alcohol on an empty stomach.²³⁷ However, in the entire population of drinking drivers, these limits can be expected to be much wider.

5.2.7.2 Michaelis–Menten Model

Because the class I ADH enzymes have a low k_m (2 to 5 mg/dL) for ethanol they become saturated with substrate after one to two drinks.^{221,222} The rate of disappearance of ethanol from blood therefore follows zero-order kinetics over a large segment of the post-absorptive elimination phase (Figure 5.2.13).^{236,237} When the BAC decreases below about 10 mg/dL, the ADH enzymes are no longer saturated and the curve changes to a curvilinear disappearance phase (first-order kinetics).^{221–223,239} However, these low BACs are not very relevant when forensic science aspects of ethanol are concerned.

It was first demonstrated by Lundquist and Wolthers²⁴⁰ that the entire post-absorptive elimination phase (zero-order and first-order stages) might be rationalized by an alternative pharmacokinetic model, namely, that of saturation kinetics.^{223,239} Thanks to the availability of a highly sensitive ADH method of analysis, much lower blood-alcohol concentration (<10 mg/dL) could be reliably determined. These investigators from Denmark fitted their BAC–time data to the Michaelis–Menten (M-M) equation and from its integrated form they arrived at the parameters V_{\max} and k_m that described the enzymatic reaction.²⁴⁰ This application of nonlinear saturation kinetics of ethanol was thereafter strongly advocated by many specialists in pharmacokinetics, among others, Wagner, Wilkinson, and their colleagues^{221,222,241–243} and values of 22 mg/dL/h and 5 mg/dL were suggested for V_{\max} and k_m , respectively.²²² Although the use of M-M kinetics has found some support among forensic scientists,^{243,244} others have not considered this necessary for actual casework because so many other variable factors and uncertainties influence the absorption, distribution, and elimination pattern of

ethanol.²⁴⁴ Moreover, the mathematical concepts needed to understand and apply M-M kinetics are much more challenging than those necessary to derive the Widmark equation. Explaining the scientific principles of pharmacokinetic multicompartment models and nonlinear kinetics to a judge and jury is a daunting task. Moreover, the idea of multiple enzyme systems being involved in the metabolism of ethanol including racial and ethnic differences and polymorphism might overly complicate the situation.^{245,246} The contribution of various isozymes of ADH as well as the higher k_m microsomal CYP2E1 pathway for disposal of ethanol after chronic ingestion (metabolic tolerance) explains the faster rate of clearance from blood in binge drinkers.^{201,204} Furthermore, the contribution from several enzyme systems is not strictly compatible with the conditions assumed to apply for application of the classical M-M equation.

5.2.7.3 First-Pass Metabolism and Gastric ADH

About 20 years ago, considerable attention was drawn to the possibility that metabolism of ethanol occurred also pre-systemically in the gastric mucosa.^{247–252} Accordingly, part of the dose of ethanol ingested was broken down before reaching the systemic circulation and this was thought to involve an enzymatic oxidation process taking place in the gastric mucosa. Pre-systemic removal of an administered drug is important to understand and has implications for therapeutic efficacy. However, the liver, which contains most of the metabolizing enzymes, was considered the primary site for first-pass metabolism (FPM) of ethanol to occur. The magnitude of FPM tended to exhibit large intersubject variations and was dose dependent and strikingly influenced by speed of gastric emptying as well as fed–fasted state.²⁵² FPM was more pronounced after very small doses of ethanol (0.15 to 0.3 g/kg) when this was consumed about 1 h after eating a meal.^{248,249} Food tends to delay stomach emptying thus allowing more time for ethanol metabolism by enzymes located in the gastric mucosa.

Distinguishing between pre-systemic oxidation of ethanol occurring in the stomach as opposed to the liver proved a very difficult task and much debate arose about the significance of gastric ADH compared with hepatic ADH as the site for FPM.^{136,250–252} Some workers were adamant about the importance of gastric FPM of ethanol whereas others challenged its importance in the overall disposition of ethanol in the body.^{250–253} The argument against rested in part on the fact that gastric ADH represented only a small fraction of the total amount of hepatic ADH and also the complex nature of M-M kinetics especially at the low BAC reached after small doses were ingested.²⁵⁰ The main advocates of gastric ADH and its role in FPM of ethanol had failed to consider the critical importance of stomach emptying and effective clearance of ethanol at low substrate concentrations.^{250–252} Factors that influence the rate of absorption of alcohol (food, drugs, type of beverage, posture, time of day) also influence the concentration of alcohol entering the portal venous blood and the degree of saturation of ethanol-metabolizing enzymes in the liver.^{245–252}

Interest in FPM and gastric ADH escalated considerably when several publications appeared showing that commonly used medications, such as aspirin and H_2 -receptor antagonists (cimetidine and ranitidine), when combined with small amounts of alcohol, resulted in higher C_{max} and area under the curve (AUC) compared with no-drug or placebo control treatment.^{253–256} These drugs were shown to block activity of gastric ADH under *in vitro* conditions (e.g., in biopsies from the stomach) but the effects *in vivo* were less clear-cut.²⁵⁷ Proponents of the role of gastric ADH in FPM of alcohol argued that this represented a protective barrier against some of the toxic effects of ethanol that cause organ and tissue damage.²⁵⁸ If this barrier was weakened or removed by various common medications, this would result in greater exposure of inner organs to ethanol and a higher than expected C_{max} and, accordingly, a more pronounced impairment of body functions.^{253–256,258} Because the activity of gastric ADH was lower in women, Asian populations, and also in alcoholics, these groups of people were thought to be more vulnerable to the toxic effects of moderate drinking.^{249,259} This conclusion proved too hasty because a flood of articles appeared challenging the notion of drug-induced effects on gastric FPM of ethanol.^{260–265} Indeed, these newer

studies incorporated an improved experimental design with many more volunteer subjects and a wider range of alcohol doses, times of day, and intake with or without food.^{260–265}

What did emerge from this new wave of interest in the clinical pharmacokinetics of ethanol was strong and convincing information for large inter- and intra-individual variations in the pharmacokinetic profiles of ethanol especially when small doses (0.15 to 0.3 g/kg) were ingested after a meal.^{266–268} The biological variation in blood-alcohol profiles was particularly evident when small doses of alcohol were ingested together with or after a meal.^{269,270}

5.2.7.4 Food and Pharmacokinetics of Ethanol

The presence of food in the stomach before drinking retards the absorption of ethanol from the gut by delaying gastric emptying.^{271–273} After a meal, the C_{\max} was considerably lower and the impairment effects of ethanol diminished compared with drinking the same dose on an empty stomach.²⁷³ The reduced bioavailability of ethanol did not seem to depend on the composition of the meal in terms of its protein, fat, or carbohydrate content.^{274–276} The altered bioavailability of ethanol with food in the stomach before drinking obviously has consequences when the apparent volume of distribution of ethanol and other kinetic parameters are evaluated, such as AUC. The dramatic lowering of C_0 in the fed state means that the ratio dose/ C_0 might increase to reach an impossible nonphysiological result (>1.0) compared with the value expected of 0.7 in men and 0.6 in women. The notion of a “loss of ethanol” when drinking occurred after a meal was observed by Widmark,¹⁰⁹ and he proposed that the mechanism might involve chemical reaction of ethanol with constituents of the food. However, a more modern explanation for this food-induced lowering in the bioavailability of ethanol is presystemic oxidation by gastric and/or hepatic ADH.^{274,275}

Figure 5.2.14 shows individual BAC curves after 12 male subjects drank 0.8 g/kg in the morning after an overnight fast.²⁶⁸ Both C_{\max} and t_{\max} varied widely between individuals. The time to reach the C_{\max} ranged from 0 to 150 min after the end of drinking. Those subjects with very slow rates

Figure 5.2.14 Individual concentration–time profile of ethanol in venous blood for 12 healthy men who drank 0.80 g ethanol per kg body weight in 30 min after an overnight fast.

Figure 5.2.15 Mean blood-alcohol profiles after eight healthy men drank alcohol (0.80 g/kg in 30 min) either on an empty stomach or immediately after eating breakfast.

of absorption might have experienced a pyloric spasm so that the absorption took place through the stomach as opposed to the duodenum and jejunum where rapid absorption occurs.

The impact of food and body composition on BAC–time profiles for various drinking scenarios was recently the subject of a comprehensive review by Kalant.²⁷⁷ Ingestion of food immediately before or together with alcohol resulted in a lower C_{\max} compared with drinking the same dose on an empty stomach. This lowering effect does not seem to be related to the composition of the meal in terms of macronutrients (protein, fat, or carbohydrate), but instead the size of the meal is seemingly more important.²⁷⁴ The delayed gastric emptying meant a slower delivery of alcohol into the small intestine, the site of rapid absorption into the portal blood, and therefore a longer exposure to gastric mucosal ADH thus enhancing the changes of gastric FPM of alcohol. Moreover, the role of FPM, whether gastric or hepatic, is small and highly variable and much depends on the dose of alcohol administered. After very small doses (<0.3 g/kg) FPM is more pronounced compared with moderate social drinking when BACs in the forensic relevant range (50 to 80 mg/dL) are reached.²⁷⁷

The BAC traces shown in Figure 5.2.15 demonstrate a marked effect of eating a meal before drinking. Both the C_{\max} and also the area under the concentration–time profile are considerably lowered compared with drinking the same dose on an empty stomach.¹⁸⁹ Here the subjects drank 0.8 g ethanol per kg either after an overnight (10 h) fast or immediately after eating a standardized breakfast. Drinking in the fed state also results in a faster metabolism of ethanol as reflected in the shorter time of 1 to 2 h needed to reach zero BAC.¹⁸⁹ This accelerating effect of a meal on the elimination rate of alcohol from blood was confirmed even when the alcohol was given intravenously.^{278,279} The mechanism of food-induced acceleration of ethanol metabolism might be related to an enhanced hepatic enzyme activity in a well-nourished organism. Furthermore, eating a meal is known to increase liver blood flow, which also facilitates a more rapid clearance of ethanol from the bloodstream at low ethanol concentrations.^{275,276,278}

5.2.8 Concluding Remarks

Harmful and hazardous consumption of alcohol is increasing worldwide owing to, among other things, the lowering of excise taxation in some countries and longer opening times for bars and restaurants in others.⁶ History has shown that deaths attributable to overconsumption of alcohol generally increase as a function of total consumption of alcohol in a population.^{5,6} Chronic heavy

drinking eventually leads to a wide spectrum of disease states and health disorders particularly liver diseases including hepatitis, cirrhosis, and death.²⁸⁰ Acute inflammation of the pancreas is another consequence of heavy drinking, not to mention a host of unintentional injuries associated with drunkenness that require emergency medical treatment.²⁸⁰ Drinking five drinks or more on one occasion is considered binge drinking, and might result in acute intoxication and drunkenness and trigger different kinds of reckless behavior, such as unsafe sex, drunk driving, aggressiveness, and family violence.^{7–10} There is not the slightest doubt that testing for alcohol will remain the most frequently requested procedure from toxicology laboratories for a long time to come.

Few substances can be measured with such a high degree of accuracy, precision, and selectivity as the concentration of ethanol in a person's blood.¹⁷ The method of headspace gas chromatography is the gold standard and can be used to analyze a wide range of volatile substances in body fluids besides ethanol.^{281,282} Making duplicate determinations is an effective safeguard against various mishaps that might occur during sample preparation and analysis. The aliquots of blood should whenever possible be taken from two separate Vacutainer tubes, which will help to minimize the risk of sample mix-up during processing. To enhance the analytical selectivity, the duplicates should be run on different chromatographic systems, thus yielding different retention times for the substances of interest.^{17,23–25} Alternatively, an independent analytical method such as enzymatic or chemical oxidation or mass spectrometry might be used in parallel with HS-GC to enhance specificity for ethanol.^{131–133}

More attention should be given to pre-analytical factors that might influence precision and accuracy of the results of ethanol determination. This includes preparation of the subject, the way the blood sample was drawn including the sampling site and the skin disinfection used, as well as the kind of Vacutainer tubes and the preservatives they might contain. Things like the ambient temperature conditions, the mode and duration of transportation of blood specimens to the laboratory, and the condition of the blood sample on arrival (volume submitted and whether coagulated or not) are of concern. The situation is compounded when blood samples are taken from victims of traffic accidents who might require emergency hospital treatment including the administration of drugs or intravenous fluids to counteract shock. It is important to remember that the result of a chemical or biochemical test is only as good as the sample received for analysis. When the analytical result is close to the legal limit for driving, small errors that creep into the analytical procedures might make the difference between punishment or acquittal in borderline cases. Thus, pre-analytical factors are just as important to control and document as analytical factors.

In forensic casework when the BAC exceeds 0.2 g/L (20 mg/100 mL), the elimination of alcohol from blood occurs at a constant rate per unit time (zero-order kinetics) as was first proposed by Widmark.^{190,209} From knowledge about the distribution volume of ethanol and the measured BAC, it is easy to calculate the amount of alcohol absorbed and distributed in the body at the time of blood sampling. Also if the time of starting to drink is known, then the total amount of alcohol consumed can be calculated by adding on the amount of alcohol eliminated through metabolism.²⁸³ A good rule of thumb is that the rate of ethanol elimination from the whole body for a moderate drinker is approximately 0.1 g/kg body weight per h and this rate seems to be independent of gender.^{284,285} Making a back-extrapolation of a person's BAC from the time of sampling to the time of driving is a dubious practice.²⁸⁶ Without knowledge of the prior drinking scenario, including the timing and quantity of alcohol in the last drink, it is difficult to predict with certainty when C_{\max} occurs. Consideration should also be given to inter- and intra-individual variations in the pharmacokinetic parameters of ethanol, especially the rate of alcohol disappearance from the bloodstream.^{186,187}

Warnings about adverse drug–alcohol interactions and the risk of experiencing an unexpectedly high BAC after moderate drinking owing to concomitant use of medication such as aspirin and antacids (ranitidine and cimetidine) have been much exaggerated.²⁰⁰ The magnitude of such an effect measured in percent was greatest after drinking very small doses of alcohol 1 h after subjects ate a fatty meal.^{248,249} However, it is worth reiterating that small absolute increases in C_{\max} between drug-treated and control group (e.g., 5 mg/dL) yield large percentage differences when the denom-

inator of the ratio is low (e.g., 15 mg/dL); this corresponds to a 33% change. When subjects drank small doses of ethanol (0.15 g/kg), repetitively (four times) over a few hours, which is more like social drinking conditions, after medication with Zantac (ranitidine), both the C_{\max} and AUC were higher compared with a placebo control treatment.²⁸⁷ However, this observation still needs to be confirmed by other investigators. The authors of the study, which was published in a reputable scientific journal, concluded that social drinkers who might be medicated with ranitidine should be warned of the risk of developing unexpected functional impairment after drinking amounts of alcohol they might normally consider safe. Unfortunately, tests of functional impairment were not included in the study design so the warning is speculative and unfounded.²⁸⁷

The inter- and intra-individual differences in pharmacokinetics of alcohol were recently reviewed with major focus on Michaelis–Menten and multicompartment models.²⁸⁸ Some investigators advocate use of more complex three-compartment models to explore the disposition and fate of alcohol in the body and to explain these processes in quantitative terms.^{289–292} Within the forensically relevant range of BAC (20 to 300 mg/dL), the zero-order kinetics of ethanol first introduced by Widmark roughly 70 years ago still remains valid. Age and gender differences in the pharmacokinetics of ethanol are largely accounted for by differences in total body water (TBW) and therefore the distribution volume of ethanol (Widmark's r factor or V_d).²⁷⁷ The notion of a significant gastric first-pass metabolism, including racial- and gender-related differences, has been much exaggerated and is only relevant after tiny doses of alcohol (<0.3 g/kg) are ingested in the fed state.^{250–252} After moderate doses of alcohol consumed on an empty stomach, the bioavailability of ethanol is close to 100% and under these conditions TBW can be calculated by ethanol dilution, which speaks against any significant first-pass metabolism.^{47,190,277} Ethanol's special physicochemical and physiological properties means that a person's BAC can be interpreted in relation to the amount of alcohol ingested.²⁸³ Such calculations are not feasible for other drugs of abuse.

This overview has made it abundantly clear that ethanol is no simple drug, neither in terms of its pharmacokinetics nor its pharmacodynamics and mechanism of action on the brain. The costs to society for treatment and rehabilitation of people with alcohol problems are astronomical.²⁹³ The entire field of biomedical alcohol research with the main focus on alcohol-related pathology was recently published in three volumes.²⁸⁰ This comprehensive handbook is the latest rendition of basic and clinical aspects of the alcohol research literature and is well worth referencing.²⁸⁰

5.3 POST-MORTEM ALCOHOL — ASPECTS OF INTERPRETATION

Derrick J. Pounder, M.D.¹ and Alan Wayne Jones, D.Sc.²

¹ Department of Forensic Medicine, University of Dundee, Scotland, U.K.

² Department of Forensic Toxicology, University Hospital, Linköping, Sweden

5.3.1 Introduction

In post-mortem toxicology, the sample most commonly submitted for analysis is blood and the most frequently encountered substance is alcohol. The technical details and procedures for measuring ethanol in blood and other body fluids obtained from a corpse are essentially the same as those used when analyzing specimens from the living. However, the interpretation of the analytical results obtained from autopsy samples is confounded by problems such as the lack of homogeneity of blood samples, microbial alcohol production post-mortem, alcohol diffusion from gastric residue and contaminated airways, and the lack of or unreliability of information on the clinical condition of the person immediately prior to death. On the other hand, autopsy offers opportunities for sampling body fluids and tissues not accessible or not readily available in the living. Sampling of blood from multiple vascular sites, the vitreous humor of the eye, gastric contents, sequestered hematomas, as well as bile, brain, skeletal muscle, cerebrospinal fluid, and liver are all possible. Nevertheless, multiple sampling at autopsy can only partly compensate for the increased interpretative difficulties created by the various post-mortem confounding factors. As a result it is necessary to apply a greater degree of caution in the interpretation of post-mortem ethanol analyses and to

take into account the totality of the available information, which should always include not only the results of the autopsy examination but also the scene of death examination and anamnestic data. A single autopsy blood ethanol concentration is commonly uninterpretable without concurrent vitreous humor and urine ethanol concentrations, as well as information gleaned from the scene of death and case history.

5.3.2 Post-Mortem Specimens for Alcohol Analysis

Within a few hours of death the blood within the vascular system clots and simultaneously there is clot lysis. The effectiveness of the clot lysis will determine whether a blood sample obtained at autopsy is clotted, or completely fluid, or partly clotted and partly fluid. The fibrin clots invariably entrap large numbers of red blood cells so that the resulting clot is relatively red cell rich and serum poor. Occasionally the heart and great vessels may contain a large two-layered clot, the lower part typically red clot and the upper part pale yellow rubbery clot largely devoid of red cells (so called “chicken fat”). Consequently “blood samples” obtained at autopsy are variable in their red cell and protein content and this will have some influence on the measured ethanol concentration since ethanol is distributed in the water portion of blood. Blood obtained from limb vessels is most likely to be fluid and largely devoid of clots and therefore provides as homogeneous a sample for analysis as can be hoped for. The presence of blood clots will not necessarily have a negative influence on the accuracy of the blood alcohol analysis using headspace gas chromatography.¹

Serum and plasma contains approximately 10 to 15% more water than whole blood. Since ethanol is distributed in the water portion of blood it can be expected that the concentration in plasma is approximately 10 to 15% higher than the corresponding whole blood concentration. This should be borne in mind whenever alcohol has been measured in serum or plasma in hospital prior to death or where a pre-mortem hospital sample of serum or plasma is subsequently analyzed for alcohol.

In 134 blood samples from healthy men and women² the mean blood alcohol concentration (BAC) was 105 mg/dL (range 22 to 155) and the mean serum alcohol concentration was 121 mg/dL (range 25 to 183) with a mean serum:blood ratio of 1.15 (range 1.10 to 1.25, standard deviation, SD, 0.02); 3 of the 134 serum:blood ratios were between 1.21 and 1.25. A larger study on 235 subjects³ produced a similar mean serum:blood ratios of 1.14 with a range of 1.04 to 1.26 and a normal distribution with SD of 0.041. Ethanol concentration in red blood cells was reported in 167 of these subjects and ratio red cells:blood ethanol ranged from 0.66 to 1.00 with a mean of 0.865 and a negatively skewed distribution with an SD of 0.065. Given these data it is evident that there may be significant differences in ethanol concentrations between different blood samples obtained at the same time from the same corpse, since an autopsy “blood” sample may range in composition from being largely red cells at one extreme to largely plasma at the other. However, in practice, most autopsy blood samples will tend to be plasma rich rather than red blood cell rich because autopsy sampling procedures tend to avoid clots and favor clot-free fluid.

The water content of whole blood decreases post-mortem, and because ethanol is distributed only in the water phase of the body, this will cause the BAC to decrease. In a study of 71 cadavers⁴ with a blood sample taken within 10 h of death (mean 2.1 h, range 0 to 9.6 h) the water content ranged between 72.4 and 89.3%, mean 80.4%, which is closely similar to the water content of blood from living persons (79.9 to 82.3% for women and 77.5 to 80.6% for men). Second samples taken from the same cadavers from 8 to 229 h post-mortem had a lower water content ranging between 64.4 and 88.0%, mean 74.0%. However, differences in blood ethanol concentration between the two sampling times was more strongly influenced by other post-mortem factors, such as putrefaction, rather than by water content changes, so that correcting a post-mortem blood alcohol for water content is not generally recommended.

5.3.3 Blood Alcohol Concentration

Ethanol is a central nervous system depressant drug exerting its effects in part via the GABA_A inhibitory receptor. At very high BACs, stupor is followed by coma and then paralysis of the respiratory center in the brain stem so that breathing stops and death ensues. The lethal range of blood ethanol concentration is based on published case reports of human fatalities and the experimentally derived LD₅₀ values of 500 to 550 mg/dL in rats, guinea pigs, chickens, and dogs.⁵ However, a review of actual cases suggests that a concentration of 250 mg/dL might be potentially lethal rather than the higher figures commonly quoted.⁶ In a retrospective review of 693 deaths attributed to acute alcohol poisoning, the mean BAC in femoral venous blood at autopsy was 360 mg/dL and the 5th and 95th percentiles were 220 and 500 mg/dL.⁷ (For fatal blood ethanol levels in various series, see Niyogi.⁸) The often quoted lethal blood ethanol range of above 400 or 450 mg/dL may only apply to uncomplicated deaths as a result of acute alcohol poisoning in inexperienced drinkers. The complexity of interpreting the significance of high blood ethanol concentrations at autopsy is illustrated by a review⁹ of fatalities with blood ethanol above 300 mg/dL. This study disclosed 502 cases attributable to acute ethanol poisoning alone but 24 resulting from well-documented natural causes, 260 from obvious trauma or violence, and 28 with a combination of a high blood ethanol and additional contributing or related abnormalities. An unusual form of sexual gratification involved self-administration of an alcohol-containing enema (klezmomania), which proved fatal with a BAC of 400 mg/dL found at autopsy following a wine enema.¹⁰

In a series of 115 deaths attributed to acute alcoholism 59% showed some asphyxial element, either postural asphyxia (positional asphyxia) or inhalation of vomit.⁶ Since acute alcohol intoxication may induce vomiting and also suppresses the gag reflex, as part of its cerebral depressant effect, there is a high risk of inhalation of vomit. Alcohol-related deaths associated with an asphyxial element may show considerably lower BACs than uncomplicated alcohol poisonings. For this reason it is particularly important to have accurate documentation of the position of the body as found and any evidence of inhalation of vomitus at the scene of death, since passive regurgitation of gastric contents and contamination of the airways may occur post-mortem during removal of the body to the mortuary. In many of these deaths in which asphyxia is a contributing factor the urine alcohol is considerably higher than the blood alcohol suggesting that the mechanism of death was coma resulting from a high BAC and subsequent respiratory embarrassment and anoxia. In such fatalities the BAC observed at autopsy is not necessarily the same that caused death owing to ongoing metabolism up to the time of death.⁶ The diagnostic features of accidental postural asphyxia are a body position that compromises breathing, such as abnormal neck flexion or limitation of chest movement, together with evidence of the accidental adoption of that position and an explanation for failure to escape, such as alcohol intoxication, in the absence of another explanation for the death.¹¹ Acute alcohol intoxication is a significant risk factor for this mode of death accounting for 22 of 30 cases in one study.¹²

A high autopsy blood ethanol concentration, although indicating chemical intoxication at the time of death, does not necessarily imply that there were observable clinical manifestations of drunkenness and this is particularly so in chronic alcoholics.¹³ Alcohol abusers develop tolerance to alcohol to the extent that they can maintain very high blood ethanol concentrations in the potentially lethal range. In an Australian study¹⁴ blood alcohol levels were determined in chronic alcoholics presenting to a detoxification service. Of the 32 subjects, all appeared affected by alcohol with 23 showing altered mood or behavior, 6 appearing confused, and 3 drowsy but none was stuporous or comatose. All displayed ataxia and dysarthria of varying degrees. The blood ethanol concentration ranged from 180 to 450 mg/dL with a mean of 313 mg/dL and 26 of the 32 were above 250 mg/dL. A similar Swedish study¹⁵ identified 24 patients who attended a hospital casualty department and were found to have blood ethanol concentrations above 500 mg/dL. Of the 16 patients for whom there were complete data available, 8 were either awake or could be aroused by nonpainful stimuli. All left the hospital alive within 24 h. It is suggested that this tolerance to high

blood ethanol levels seen in chronic alcoholics is primarily the result of neuronal adaptation. Physical dependence on ethanol, as demonstrated by the development of withdrawal signs and symptoms on stopping drinking, similarly indicates the existence of an adaptation process.

There are anecdotal descriptions of alcoholics surviving remarkably high levels of blood alcohol. In one instance,¹⁶ a 24-year-old female chronic alcoholic presented at the hospital with abdominal pain. She was agitated and slightly confused but alert, responsive to questioning, and orientated to person and place, though unclear as to time. Her serum ethanol was 1510 mg/dL, which corresponds to a concentration in whole blood of about 1313 mg/dL (1510/1.15). After 12 h treatment with intravenous fluids, electrolyte replacement, chlordiazepoxide, and intensive care monitoring, she felt well, and was symptomless at discharge 2 days later. Similarly, a 52-year-old, 66-kg male was found unconscious in a bar with a blood ethanol concentration of 650 mg/dL and survived with minimum treatment comprising protection against aspiration and the occasional use of oxygen.¹⁷ A 23-year-old, 57-kg female chronic alcoholic, who was admitted to the hospital in a comatose state with a blood ethanol level of 780 mg/dL, had apparently consumed 390 mL of absolute alcohol in the form of a bottle of bourbon. She was discharged 11 h later with a blood ethanol level of 190 mg/dL; the disappearance of ethanol from her blood seemingly followed a logarithmic function.¹⁸ Two further case reports describe more stormy clinical courses but with survival, one with a serum ethanol level of 1127 mg/dL,¹⁹ another with a blood ethanol level of 1500 mg/dL.²⁰ One individual arrested in Sweden for drunk-driving had a BAC of 545 mg/dL.²¹ This tolerance to high blood ethanol concentrations seen in chronic alcoholics makes it difficult to interpret the significance of a blood ethanol level obtained at autopsy from such a person.

On the other hand, nonlethal levels of ethanol may be of particular significance in some types of death. Ethanol adversely affects thermal regulation and, depending upon the ambient temperature, may cause either hypothermia or hyperthermia.²² There is a large body of experimental and clinical data available regarding the hypothermic effect of alcohol on both animals and humans at different degrees of cold exposure. In deaths related to acute alcohol poisoning, a mean BAC of 170 mg/dL in hypothermia-associated deaths contrasted with a much higher mean BAC of 360 mg/dL in deaths without associated hypothermia.²³ Alcohol consumption accelerates body heat loss by inducing dilatation of peripheral blood vessels and relaxing muscles, thereby inhibiting shivering thermogenesis. Heat loss is further facilitated by behavioral effects consequent on a feeling of warmth and comfort, and central nervous system depression. At a biochemical level, alcohol may inhibit the protective acute ketogenesis induced by the effects of hypothermia and so shorten the survival time.²⁴ Deaths from hypothermia associated with sobriety or a BAC of less than 100 mg/dL have a higher frequency of the macroscopic autopsy signs of hypothermia — bright red lividity, violet patches over the knees and elbows, acute gastric mucosa erosions, pancreatitis, and paradoxical undressing — than cases with a BAC greater than 100 mg/dL, suggesting that intoxication is associated with more rapid death before visible pathological signs develop.²⁴ The importance of ethanol in hyperthermic deaths is less well appreciated but illustrated by Finnish sauna fatalities. In a series of 228 hyperthermic deaths (221 sauna related) alcohol had been consumed in 192 cases and the consumption was categorized as “heavy” in 61.²⁵ Similarly, complex cerebral dysfunctions induced by alcohol are thought to be significant in the syndrome of sudden, alcohol-associated, cranio-facial traumatic death.²⁶ In this syndrome individuals who have collapsed and died at the scene of an assault are found at autopsy to have facial trauma insufficient to account for the death together with a high but nonlethal BAC.

The simultaneous presence of another drug with ethanol further complicates the interpretation of the concentrations measured at autopsy. Investigations into drug–alcohol interactions are complex because these interactions are influenced by the timing of administration of alcohol relative to the drug and the specific dosages. As well as being oxidized by alcohol dehydrogenase (ADH), ethanol is metabolized to acetaldehyde by a microsomal enzyme, cytochrome P4502E1 (CYP2E1). This same enzyme is involved in oxidative metabolism of a wide range of endogenous and exogenous substances, including therapeutic drugs, with the result that an important mechanism

for drug–alcohol interactions involves either an inhibition or induction of this enzyme. After taking a large acute dose of alcohol, the ethanol molecules compete with other drugs for detoxification enzymes. On the other hand, chronic consumption of large amounts of alcohol causes induction of the enzyme system so that alcoholics acquire an enhanced capacity for the metabolism of drugs via this system. Alcoholics are more prone to suffer from hepato-toxicity from taking acetaminophen (paracetamol) owing to their more active CYP2E1 detoxification enzymes, which convert acetaminophen into a chemically reactive and toxic intermediate compound, *N*-acetyl-*p*-benzoquinone imine (NAPQI).²⁷

Chloral hydrate, one of the oldest sedative hypnotic drugs, has a complex interaction with ethanol. In the liver, chloral hydrate is rapidly reduced to its pharmacologically active metabolite 2,2,2-trichloroethanol, and this reaction is facilitated by the excess NADH (nicotinamide adenine dinucleotide) produced in the liver during the metabolism of ethanol. The pharmacologically active trichloroethanol is either conjugated with glucuronic acid and then excreted in the urine or is oxidized by ADH to an inactive metabolite, trichloroacetic acid. This latter ADH reaction is inhibited by the presence of ethanol, which competes for binding sites on the enzyme. The net result of both of these interactions with alcohol is that the effect of chloral hydrate on the individual is more intense and prolonged.²⁷

Ethanol is a central nervous system depressant and a similar synergistic effect is found for other hypnotic drugs as well as antidepressants and narcotic analgesics so that allowance for ethanol–drug synergism is necessary when blood concentrations measured at autopsy are interpreted.²⁸ In general, any drug or chemical agent with psychoactive properties, that is, with its site of action in the central nervous system, has the potential for pharmacodynamic interaction with ethanol. The toxicity of the painkiller propoxyphene is enhanced in alcohol abusers and binge drinkers. Although the mechanism of the interaction with ethanol is not completely understood, it appears to be related to synaptic activity at GABA and opiate receptors with additive effects on the depression of respiration. Sedative-hypnotic drugs, which are widely prescribed, are obvious candidates for interaction with ethanol, owing to the similar mechanism and sites of action in the brain, namely, the GABA receptor complex. Examples of sedative-hypnotics exerting a pharmacodynamic interaction with ethanol include barbiturates and benzodiazepines. Deaths resulting from the combined use of large doses of alcohol and barbiturates are well recognized. However, in case of fatalities it has proved difficult to establish an added toxic effect from the concurrent use of diazepam with alcohol, so that in cases of acute alcohol poisoning the blood ethanol concentration is about the same, with or without the presence of diazepam.²⁹

The alcohol flush reaction exhibited by many Japanese and other Asians when they drink alcoholic beverages is a direct consequence of acetaldehyde accumulation in the blood. Acetaldehyde reacts with β -adrenergic receptors of the autonomic nervous system leading to violent and unpleasant vasomotor responses. These individuals inherit a defective form of the enzyme acetaldehyde dehydrogenase (ALDH) and as a result are genetically prone to react strongly after drinking small amounts of alcohol, so that in effect they are equipped with a natural aversion to alcohol. A fatality has been reported in a Japanese subject with this inherited defect resulting in abnormally high concentrations of acetaldehyde after consumption of ethanol.³⁰ Disulfiram (tetraethylthiuram disulfide or Antabuse®) inhibits ALDH and is used in aversion therapy for treating alcoholics, although its clinical effectiveness has been debated. In a person taking the drug, subsequent ingestion of alcohol produces numerous unpleasant symptoms as a result of the toxic accumulation of acetaldehyde. Fatalities have been reported after reaching relatively low blood ethanol concentrations and with acetaldehyde in blood at concentrations between 12 and 41 mg/L.³¹ When the edible inky cap mushroom (*Coprinus atramentarius*) is mistakenly eaten at the same time alcohol is consumed, the result is an Antabuse-like reaction owing to the presence of an unusual amino acid protoxin, coprine (*N*5-1-hydroxycyclopropyl-L-glutamine), which is broken down in the body to 1-aminocyclopropanol, an inhibitor of hepatic ALDH. Enzyme inhibition generally persists for about 72 h but may continue for 5 days, so consumption of ethanol during this period might produce

an unpleasant Antabuse-like reaction. Metronidazole has been reported to cause death when taken with ethanol as a consequence of an Antabuse-like reaction,³² but others have suggested that there might be an allergic reaction to the drug modified by the presence of alcohol.³³ Other prescription drugs that might produce an Antabuse-like reaction are chlorpropamide and tolbutamide, both oral hypoglycemic agents used to treat diabetes.

Cocaethylene is biosynthesized during the metabolism of cocaine in individuals with elevated BACs. This compound passes the blood–brain barrier to exert its pharmacological effects through the dopamine receptor thus enhancing the feelings of euphoria. Since the elimination half-life of cocaethylene is longer than for cocaine, it prolongs the effects of the drug on the individual. Several studies have suggested that when cocaine is taken together with ethanol, the risk of cardiotoxicity^{34,35} and a fatal outcome³⁶ is increased. It has been suggested that ethanol enhances the acute toxicity of heroin and that ethanol use indirectly influences fatal heroin overdose through its association with infrequent (non-addictive) heroin use and thus a reduced tolerance to the acute toxic effects of heroin.³⁷ Although it has been proposed that carbon monoxide and ethanol may have an additive affect there is no conclusive evidence of this.

5.3.4 Vitreous Alcohol

Analysis of vitreous humor (VH) is useful to corroborate a post-mortem BAC and this helps to distinguish ante-mortem intoxication from post-mortem synthesis of alcohol. VH can serve also as an alternative post-mortem specimen for alcohol analysis if for some reason blood is unavailable or contaminated. In most cases, the specimen of eye fluid is easily obtained and can be sampled without a full autopsy. Vitreous humor is a clear, serous fluid which is easy to work with analytically. Its anatomically isolated position protects it from bacterial putrefaction. In microbiological studies of vitreous obtained from 51 cadavers between 1 and 5 days post-mortem it was found that none of the samples contained large numbers of bacteria and only one contained fungi.³⁸

The predictive value of a known vitreous humor alcohol concentration (VHAC) in estimating an unknown BAC in an individual case remains contentious, despite many studies.^{39–50} Various formulae have been proposed, including a simple conversion factor, to predict BAC from VHAC but these do not take into account the uncertainty of the prediction for an individual subject. In one case series⁵¹ simple linear regression was applied with BAC as outcome y variable and VHAC as predictor x variable (range 1 to 705 mg/dL). The regression equation was $BAC = 3.03 + 0.852 \text{ VHAC}$ with 95% prediction interval $\pm 0.019 \sqrt{[7157272 + (\text{VHAC} - 189.7)^2]}$.

The practical application of the regression equation is shown in Table 5.3.1. Set out are the VHAC values that predict key BAC values of 80 and 150 mg/dL as the mean, or the minimum value at either the 95% or 99% prediction interval for the determination of a single BAC value. The prediction interval is too wide to be of much practical use. In addition, reanalysis of the raw data from previous publications gave significantly different regression equations in most instances. From an evidential viewpoint it would be unreasonable to give an estimate of the mean BAC based on the VHAC without also providing the 95% prediction interval, which is a measure of the degree of confidence attached to the estimate in an individual case.^{52–54} Data from another large study suggest that dividing the VHAC by 2.0 would provide a very conservative estimate of the BAC, which is less than the true value with a high degree of confidence.⁵⁵

Blood has a lower water content than vitreous, which is approximately 98 to 99% water v/v, so the expectation is that the blood:vitreous alcohol ratio will be less than unity. In cases where the ratio of blood alcohol to vitreous humor alcohol concentration exceeds 1.0, the most likely explanation is that death occurred before diffusion equilibrium had been attained, which might have forensic significance.⁴¹ Animal studies^{56,57} indicate that, following intraperitoneal or intravenous injections of ethanol, BAC:VHAC ratios may be greater than 0.95 for 30 min or longer. A study of 43 fatalities⁴⁵ disclosed a bimodal distribution of blood:vitreous alcohol ratios with the first mode from 0.72 to 0.90 and a positively skewed distribution from 0.94 to 1.37. It seems that

Table 5.3.1 Prediction of Critical Values of BAC (as mean, or lower limit of 95% and 99% prediction intervals) from VHAC (mg/dL)⁵¹

Observed VHAC mg/dL	Mean	Predicted BAC mg/dL	
		95% PI	99% PI
90	80	29–131	13–147
150	131	80–182	64–198
169	147	96–198	80–214
173	150	100–201	83–217
232	201	150–251	134–268
251	217	166–268	150–284

Note: PI = prediction interval for the determination of a single BAC value. Thus for an observed VHAC of 90 mg/dL the best estimate of BAC is 80 mg/dL; there is a 95% probability that the true value of BAC is between 29 and 131 mg/dL; and a 99% probability that the true value is between 13 and 147 mg/dL.

the first mode of the distribution ratio represents the elimination phase of the blood alcohol curve and that the second mode represents the absorption phase prior to equilibrium being established.

A second study of 86 cases confirmed this bimodal distribution and suggested that a blood:vitreous ratio greater than 0.95 indicates that death had occurred before equilibrium was achieved, and therefore in the early absorptive phase.⁴⁸ The blood:vitreous ratio during this early phase had a mean of 1.09 (SD = 0.38) in contrast to the late absorptive and elimination phases where the mean was 0.80 (SD = 0.09). Others⁴⁷ failed to reproduce this bimodal distribution. However, most deaths occur during the elimination phase, and it is clear that the observation of a bimodal distribution of blood:vitreous alcohol ratios in any study depends on the inclusion of cases dying in the absorptive phase. It is likely that the proportion of absorptive phase cases included in published series has varied considerably and that this accounts, at least in part, for the differences in published BAC:VHAC ratios.

It seems reasonable to assume that ethanol may diffuse into or out of the vitreous post-mortem. The chemical constituents of embalming fluid may diffuse into the vitreous humor after a body has been embalmed. Fortunately almost all commercial embalming fluids are free of ethyl alcohol, although they commonly contain methanol. A comparison of ethanol concentrations in 38 corpses both pre- and post-embalming suggested that there was no significant change in the vitreous humor ethanol concentration in the immediate aftermath of embalming.⁵⁸ However, in one case the embalmer cleaned the globus of the eye with ethanol on a cotton swab prior to placing an eye cap into position and this caused an elevation of vitreous ethanol from 0 to 340 mg/dL. In another fatality, an unusually high VHAC was attributed to prolonged post-mortem exposure of the eye surface to alcohol-containing vomit.⁵⁹ Conversely, prolonged submersion of a body in water may result in diffusion of alcohol out of the vitreous. This was the proposed explanation for finding a zero ethanol concentration in vitreous but concentrations of 370 mg/dL in urine and 223 mg/dL in blood (blood acetone 46 mg/dL) in a man submerged in cold fresh water for about 6 weeks. In a rabbit model that duplicated these circumstances the vitreous ethanol level fell from a mean of 196 to 30 mg/dL over the 6-week period.⁶⁰

5.3.5 Urinary Alcohol

The ureteral urine, which is the urine as it is being formed, has a concentration of alcohol approximately 1.3 times that of whole blood. In fatalities the urine sample obtained is pooled bladder urine, which has accumulated over an unknown time interval between last urination and death. Consequently, the bladder urine alcohol concentration (UAC) does not necessarily reflect

the BAC existing at the time of death. Instead it reflects the average BAC prevailing during the period that urine accumulates in the bladder since it was last emptied.

Several studies have examined the range of ratios between BAC and pooled bladder UAC at autopsy. One study⁶¹ reported an average UAC:BAC ratio of 1.28:1 with a wide range of 0.21 to 2.66. In another study⁴⁴ the mean UAC:BAC ratio was 1.21:1 with a range from 0.22 to 2.07 using a direct injection gas chromatography (GC) technique and a mean ratio of 1.16:1 with a range of 0.20 to 2.10 with the more widely used headspace GC technique. In a large case series, simple linear regression analysis with BAC as outcome variable and autopsy bladder UAC as predictor variable ($n = 435$, range 3 to 587 mg/dL) gave the regression equation $BAC = -5.6 + 0.811UAC$.⁶² The 95% prediction interval around the regression line was given by the equation $\pm 0.026\sqrt{[9465804 + (UAC - 213.3)^2]}$. This shows that a BAC of 80 mg/dL was predicted with 95% certainty by a UAC of 204 mg/dL and similarly a BAC of 150 mg/dL by a UAC of 291 mg/dL. The prediction interval is very wide so that autopsy UAC has limited usefulness in predicting an unknown BAC for forensic purposes. Although an autopsy UAC should not be translated into a presumed BAC, it is possible to make a conservative estimate of the BAC existing during the time the urine was being produced and accumulated in the bladder, by dividing the observed autopsy UAC by 1.35 (or multiplying by three quarters). However, if the BAC profile was rising, which might be the case if death occurred soon after drinking ended, the calculation $UAC/1.35$ underestimates the coexisting BAC.

When both urine and blood specimens are available at autopsy, then the UAC:BAC ratio may be of interpretive value, by giving an indication of the state of alcohol absorption and elimination in the body at the time of death.⁶³ A ratio less than unity or not more than 1.2 suggests, but does not prove, the existence of a rising BAC. If the UAC:BAC ratio exceeds 1.3, this suggests that the subject was in the post-absorptive stage at the time of death. The UAC:BAC ratio in 628 deaths from acute ethanol poisoning was 1.18 (SD = 0.182) and in 647 chronic alcoholic deaths was 1.30 (SD = 0.29), suggesting that the former group died typically before complete absorption and distribution of alcohol while the latter group died typically after complete absorption and distribution.⁶⁴ However, establishing whether a deceased had consumed alcohol immediately prior to death is most easily achieved by obtaining a sample of stomach contents at autopsy and analyzing this for alcohol. A gastric contents concentration less than 500 mg/dL has been taken to indicate a post-absorptive state.⁴³ Unusually high UAC:BAC ratios reflect urine accumulation over a long period of time and extreme ratios are well recognized as occurring in delayed deaths from acute alcohol poisoning.⁶⁵ In delayed traumatic deaths post-mortem urine ethanol concentrations may help establish or exclude the role of alcohol. Urine ethanol content of 200 mg/dL may be found with no alcohol present in the blood.⁶⁶

5.3.6 Alternative Biological Samples

There have been many attempts to correlate post-mortem BACs with the concentrations of alcohol measured in a creative variety of specimens. In addition to the usual urine and vitreous humor these specimens have included saliva, cerebrospinal fluid, brain, liver, kidney, bone marrow, and skeletal muscle. All show a very wide range of variation in the ratio of the ethanol content in the target tissue or fluid compared with that in blood, making them of little value in practice. Since ethanol distribution in the body follows the distribution of body water, the ethanol content of these unconventional specimens is influenced by their water content. Cerebrospinal fluid is 98 to 99% water w/w and therefore generally will have a higher ethanol content than blood, whereas muscle, brain, liver, and kidney, with a water content of 75 to 78% w/w, will have lower concentrations of alcohol than blood. Moreover, the continuing post-mortem enzymatic activity within liver and kidney may reduce their ethanol content.

For blood alcohol levels greater than 40 mg/dL the average liver:heart blood ratio in 103 cases was 0.56, SD 0.30, with a range of 0 to 1.40.⁶⁷ However, liver is not recommended as a suitable

sample for post-mortem ethanol analysis because it is rapidly invaded by gut microorganisms and provides abundant glycogen as substrate for ethanol production by fermentation, as well as being subject to post-mortem diffusion from gastric residue. For bile, in 89 cases with blood ethanol ranging from 46 to 697 mg/dL the bile:blood ratio averaged 0.99, range 0.48 to 2.04. Bile has been suggested as superior to vitreous humor in the estimation or corroboration of a blood alcohol level,⁶⁸ but, unfortunately, bile is vulnerable to post-mortem diffusion of unabsorbed alcohol in the stomach.⁶⁹ For cerebrospinal fluid ($n = 54$, blood ethanol range 46 to 697 mg/dL) the average ratio was 1.14 and range 0.79 to 1.64.⁴³

Since ethanol impairs body functioning by its effects on the brain, it would seem logical to analyze brain tissue for alcohol at autopsy. This is not the practice for two reasons. First, the analysis of post-mortem blood is more helpful as it allows comparison with data available from living persons. Second, the brain is extremely heterogeneous so that within the brain the ethanol concentration may vary twofold to threefold between different regions; highest concentrations are found in the cerebellum and pituitary and lowest concentrations in the medulla and pons.⁷⁰ Brain tissue obtained from the frontal lobe ($n = 33$ blood ethanol range 72 to 388 mg/dL) gave an average brain:blood ratio of 0.86 with a range of 0.64 to 1.20.⁴³

5.3.7 Residual Gastric Alcohol

Opinions vary as to how much alcohol may be found in the stomach post-mortem in case material. In one series⁷¹ the highest concentration found was 2.95 g/dL and the author quoted a similar high of 5 g/dL in a previous study. In another series⁷² only 1 of 60 cases had a concentration as high as 5.1 g/dL. In a small study⁷³ the highest concentration observed was 8.7 g/dL and this was in a suicidal hanging. Given that alcohol is rapidly absorbed from the stomach, it seems likely that death must occur within about an hour or less of ingesting substantial amounts of alcohol to detect a significant residue in the stomach post-mortem.

Researchers in the 1940s and 1950s debated the suitability of heart blood for quantitative analysis of ethanol on the grounds of possible artifactual elevation resulting from post-mortem diffusion of alcohol present in the stomach at the time of death.^{74–80} Later investigations by Plueckhahn^{71,81–86} led to the conclusion that post-mortem ethanol diffusion from the stomach into the pericardial sac and left pleural cavity was significant and could contaminate blood samples allowed to pool there, but cardiac chamber blood, as such, was not susceptible to this diffusion artifact to any significant extent. However, more recent case studies and a cadaver model have shown that cardiac chamber, aortic, and other torso blood samples may be significantly affected by gastric diffusion artifact.⁷³

In one study⁸⁷ blood was obtained from the right atrium, ascending aorta, and the inferior vena cava in 307 subjects without significant decomposition and in whom the blood ethanol concentration was not less than 50 mg/dL in any sample. A total of 104 (33.9%) had one blood ethanol value 20% lower than the highest value. The most striking differences were found when gastric ethanol concentrations were greater than or equal to 800 mg/dL and with associated evidence of aspiration. In a second study⁷² blood was obtained from the femoral vein, the aortic root, and the right atrium in 60 cases with blood ethanol concentrations of 50 mg/dL or greater and no gross trauma or significant decomposition. Although the mean alcohol concentrations for the different samples were not significantly different, there were wide variations in alcohol concentration among the various blood sample sites in a number of individual cases. Of the cases, 20 (33.3%) had within-case blood alcohol differences greater than 25%; 4 had differences greater than 50%, with 1 of these cases exceeding 400%. Indeed 3 of the 4 latter cases had gastric alcohol concentrations between 1 and 5.1 g/dL and the fourth had a concentration between 0.5 and 1 g/dL, whereas, for the 60 cases as a whole, 22 were between 0.5 and 1 g/dL and 11 were above 1 g/dL. In a third study⁷³ of nine fatalities with known alcohol consumption shortly before death, two showed marked variations in blood ethanol concentrations in samples from ten sites, with ranges (mg/dL) of 97

to 238 and 278 to 1395; pericardial fluid 1060 and 686; vitreous humor 34 and 225; stomach contents 300 mL at 5.5 g/dL and 85 mL at 1.9 g/dL, respectively. These studies^{72,73,87} suggest that post-mortem diffusion of alcohol from the stomach into the blood may be a significant, although uncommon problem.

The above findings were corroborated by a human cadaver model⁷³ with multiple blood site sampling after introducing 400 mL of alcohol solution (5%, 10%, 20%, or 40% weight/volume in water) into the stomach by esophageal tube. The pattern of ethanol diffusion showed marked between-case variability but typically concentrations were highest in pericardial fluid and, in decreasing order, in left pulmonary vein, aorta, left heart, pulmonary artery, superior vena cava, inferior vena cava, right heart, right pulmonary vein, and femoral vein. Diffusional flux was broadly proportional to the concentration of ethanol used, was time dependent (as assessed by 24-h and 48-h sampling), and was markedly inhibited by refrigeration at 4°C. After gastric instillation of 400 mL of 5% ethanol for 48 h at room temperature in paired cadavers, the concentrations (mg/dL) were as follows: pericardial fluid 135, 222; aorta 50, 68; left heart 77, 26; right heart 41, 28; femoral vein 0, 0. With a 10% solution of ethanol in the stomach, concentrations (mg/dL) were pericardial fluid 401, 255; aorta 129, 134; left heart 61, 93; right heart 31, 41; femoral vein 5, 7. The very high concentrations of alcohol found in the pericardial fluid emphasize the potential for serious contamination of any blood sample allowed to pool in the pericardial sac. Introducing 50 mL of 10% alcohol solution into the esophagus after esophago-gastric junction ligation produced similar aortic blood ethanol concentrations to those seen after gastric instillation. This suggests that post-mortem gastro-esophageal reflux and diffusion from the esophagus is one mechanism for artifactual elevation of aortic blood ethanol.

Post-mortem relaxation of the gastro-esophageal sphincter permits passive regurgitation of gastric contents into the esophagus, if body position and the volume of gastric contents permit. Thereafter manipulation of the body during removal and transport might easily lead to contamination of the airways by gastric material, simulating agonal aspiration of vomitus. Alcohol in this gastric material could diffuse from the airways into the blood. An experimental study⁸⁸ demonstrated that a relatively small amount of ethanol introduced into the trachea of cadavers was readily absorbed into cardiac blood and also that there was direct diffusion from the trachea into both the aorta and superior vena cava.

5.3.8 Post-Mortem Stability and Synthesis of Alcohol

Alcohol loss from body tissues and fluids may occur post-mortem as a result of evaporation, shifts in the water content of tissues, enzymatic breakdown, and bacterial degradation. Following the death of an individual, many of the cells of the body survive for a variable time, providing the window of opportunity for tissue and organ transplantation from non-beating-heart donors. During this period of cellular life following somatic death, cellular enzymatic activity continues, ethanol is metabolized and ethanol concentrations may fall slightly. Later bacterial invasion of tissues may result in further ethanol loss from bacterial degradation of ethanol. Ethanol is both utilized and produced by microorganisms, so that bodies with high initial levels may show a decrease, and bodies with low initial levels may show an increase.⁸⁹ However, in practice it is ethanol production by bacteria that represents the principal effect and this view is supported by an animal model.⁹⁰ Determining whether ethanol identified in post-mortem blood represents alcohol ingested prior to death or was formed post-mortem as a result of microbial activity is a common problem. Ethanol formation may occur in blood putrefying in a cadaver or in blood putrefying *in vitro*. It appears that ethanol is not formed post-mortem except by microbial action. Germ-free mice do not putrefy because of the absence of microorganisms,⁹¹ and post-mortem autolysis of germ-free mice produces low levels of acetone and acetaldehyde but no ethanol. By contrast, putrefying conventional mice also produced ethanol, propionic acid, isopropyl alcohol, and *n*-propyl alcohol.⁹¹

Ethanol production in corpses⁹² takes place by a pathway opposite to that of ethanol catabolism in the living body. The necessary alcohol dehydrogenase and acetaldehyde dehydrogenase enzymes are provided by the microorganisms associated with putrefaction while the carbohydrate substrates are present in blood and tissues. The level of tissue glycogen available for post-mortem glycolysis and subsequent microbial ethanol production varies considerably between tissues. Human liver contains about 1 to 8 g glycogen/100 g wet tissue; skeletal muscle 1 to 4 g/100 g, brain from a variety of animals 70 to 130 mg/100 g and retina (ox) 90 mg/100 g (all figures calculated from dry weight assuming 75% water).⁹³ Anaerobic glycolysis produces pyruvate, the main substrate for ethanol production. Besides glucose, lactate is a source of pyruvate through the action of lactate dehydrogenase. Since lactate is found in relatively high concentrations in all post-mortem tissues (about 150 to 650 mg/100 g),⁹⁰ it may well be an important source of ethanol. A study *in vitro* with putrefying post-mortem blood under anaerobic conditions at room temperature demonstrated that ethanol formation occurred not only by way of glycolysis but also from lactate via conversion into pyruvate.⁹³ There is also evidence that ethanol might be produced by bacterial catabolism of amino acids and fatty acids.⁹⁴

Escape of large numbers of bacteria from the gut occurs in the first instance via the lymphatics and portal venous system, within a few hours after death. At room temperature bacterial contamination of the systemic circulation occurs after about 6 h, and after 24 h there is direct bacterial penetration of the intestinal wall. Generally the tissues remain relatively free of viable bacteria during the first 24 h. Trauma immediately prior to death, intestinal lesions and neoplastic disease, generalized infection, and gangrene are all conditions associated with early spread of bacteria post-mortem.⁹⁰ In a living person, ethanol may be produced by gut bacteria present in the infected intraperitoneal fluid associated with a peritonitis following a stabbing.⁹⁵ A wide variety of bacteria normally present in the gut and responsible for putrefaction can generate ethyl alcohol in blood, brain, liver, and other tissues.⁹⁶ As well as bacteria, yeasts such as *Candida albicans* may be responsible for post-mortem alcohol production.⁹⁷ *Candida* overgrowth in the gut in the living may cause intra-gastrointestinal alcohol fermentation syndrome, a rare condition described in Japan.⁹⁸ *Candida* colonization of the gut, stagnation of food, and a high carbohydrate diet allow fermentation to produce sufficient alcohol to cause intoxication to the point of illness, with a BAC of 254 mg/dL reported in one case.⁹⁸

There is considerable evidence that ethanol can be produced in corpses at levels up to 150 mg/dL after they have been stored for a few days at room temperature. In a study of 130 decomposing bodies,⁹⁹ there were 23 with presumed post-mortem ethanol production. Of these, 19 of 23 had blood ethanol concentrations of 70 mg/dL or less and the other 4 had levels of 110, 120, 130, and 220 mg/dL. Since both bacterial growth and enzyme activity is temperature dependent it is reasonable to assume that post-mortem ethanol production is inhibited by refrigeration. For example, a series of 26 in-hospital deaths refrigerated within 1 h of death and stored at 6°C for 3 to 27 h before autopsy showed no evidence of post-mortem ethanol production despite positive blood cultures in 13 cases, 7 of whom had blood glucose in excess of 20 mg/dL.¹⁰⁰ Chemical inhibitors of bacterial growth, such as sodium fluoride, prevents the production of ethanol in post-mortem specimens. As with all blood specimens intended for ethanol analysis it is recommended that post-mortem specimens should be preserved with 2% w/v sodium fluoride and that storage at temperatures above 4°C should be minimized.

Circumstances that can be expected to provide fertile ground for post-mortem ethanol production include prolonged exposure to a high environmental temperature, terminal hyperglycemia, and death from infectious disease with septicemia, natural disease such as ischemia affecting the large bowel, abdominal trauma, and severe trauma with wound contamination. Body disruption of a severity that commonly occurs in aviation accidents is associated with extensive microbial contamination and a resultant higher probability of post-mortem ethanol production. In a series of 975 victims of fatal aircraft accidents¹⁰¹ the BAC exceeded 40 mg/dL in 79 cases and of these it was considered, based on ethanol distribution in urine, vitreous humor, and blood, that 27% represented post-mortem

production and 28% ingestion, but 45% were unresolved. In such traumatic cases blood concentrations as high as 300 mg/dL might be synthesized post-mortem. In the *USS Iowa* explosion the highest ethanol concentration attributed to post-mortem fermentation was 190 mg/dL.¹⁰²

In establishing whether there is post-mortem production or *in vivo* ingestion of alcohol, circumstantial evidence and corroborative analyses of vitreous humor and urine is of considerable assistance. Although vitreous contains glucose and lactate, both substrates for bacterial production of alcohol, it is protected by its remoteness from invasion by putrefactive bacteria spreading from the gut through the vascular system. Urine is useful because it normally contains little or no substrate for bacterial conversion to ethanol. An exception occurs if the urine contains sufficient suitable substrate, such as glucose, as a consequence of some pathological abnormality, particularly diabetes mellitus.¹⁰³

After the early post-mortem period, when decomposition begins, the problem of production of ethanol increases because both decomposition and synthesis of ethanol are the result of microorganism spread and proliferation. This putrefactive phase starts about 2 or 3 days after death in a temperate climate but varies considerably depending on environmental conditions, primarily temperature. In early putrefaction when a sample of vitreous humor is still obtainable the presence of ethanol in this fluid is the best indicator of ethanol ingestion ante-mortem. The presence of ethanol in the urine, if it is available, is also a good indicator of ethanol ingestion. Once decomposition has progressed so that the vitreous is no longer available, due to collapse of the eyeballs, and blood cannot be obtained because the blood vessels are filled with putrefactive gases, then no reliance can be placed upon any sample, and interpretation of analytical results is hazardous if not impossible. In these cases anamnestic data may be more reliable than analytical data. In around 20% of decomposed bodies the ethanol detected is probably derived from endogenous sources based on its presence in blood but absence in vitreous or urine, but in many cases endogenous production cannot be distinguished from ingestion.⁹⁹ Post-mortem ethanol production in decomposed bodies results in blood or putrefactive fluid concentrations less than 150 mg/dL in over 95% of cases, but this general observation does not assist in evaluating a higher level found in an individual case.^{99,104} In decomposing bodies endogenous ethanol production may occur in the bile as well as the blood and this might be particularly marked in the sanguineous putrefactive fluid, which accumulates in the pleural cavities.¹⁰⁴

The importance of measuring ethanol concurrently in vitreous, urine, and blood samples was demonstrated in the assessment of low post-mortem BACs. A series of 381 cases with autopsy BACs less than 50 mg/dL were evaluated using the presence of ethanol in the vitreous and/or urine as indicators of ingestion rather than post-mortem production.¹⁰⁵ When the BAC was 10 to 19 mg/dL, the investigators found that 54% of cases had positive vitreous or urine ethanol concentrations (greater than 10 mg/dL); when the BAC was 20 to 29 mg/dL this percentage increased to 63%; when the BAC was 30 to 39 mg/dL the percentage was 73%, and when the BAC was 40 to 49 mg/dL, 92% of the cases had an alternative specimen positive for ethanol. Of the 165 cases where both vitreous and urine were available, more than 90% demonstrated consistent results; however, in 14 cases, there was an unexplained inconsistency with one specimen positive and the other negative.

Bacterial production of ethyl alcohol is associated with the production of other volatile compounds such as isoamyl alcohol, formaldehyde, n-propyl alcohol, isopropyl alcohol, propionic acid, acetone, acetic acid, acetaldehyde, n-butanol, sec-butanol, tert-butanol, n-butyric acid and iso-butyric acid. Of these n-butyric acid and iso-butyric acid are said to be the most common associates of ethanol produced by putrefactive bacteria.⁹⁶ Others have advocated measuring n-propanol as a marker of microbial fermentation.¹⁰⁶ However, variability in metabolic pathways between microorganisms leads to variability in the final products of glucose fermentation. Furthermore, there is no reliable quantitative relationship between these volatiles and ethanol produced post-mortem. This limits considerably the potential usefulness of measuring these other volatile products to distinguish between alcohol ingestion and post-mortem production.

A variety of biochemical approaches to the assessment of post-mortem synthesis of alcohol have been proposed. The major enzymatic pathway for disposal of ethanol is oxidative metabolism with

Class I isozymes of ADH to produce acetaldehyde and this toxic metabolite is oxidized further by ALDH to acetic acid. Very small amounts of ingested ethanol (<1%) undergo non-oxidative metabolism by three different reaction mechanisms. Like many drug molecules with hydroxyl groups, ethanol undergoes a conjugation reaction catalyzed by liver enzymes to produce ethyl glucuronide (EtG) and ethyl sulfate (EtS).^{107,108} Thus, EtG and EtS are specific metabolites of ethanol and these have proved very useful as markers of prior ethanol ingestion because elimination half-lives are much longer than for ethanol itself.^{107,108} Analytical methods for ethyl glucuronide have been considerably improved in recent years such as by using liquid chromatography–mass spectrometry.¹⁰⁹

Ethanol also reacts with a membrane-bound phospholipid to form phosphatidylethanol, and a third reaction is esterification with short-chain fatty acids to produce the corresponding esters.^{110–112} These non-oxidative metabolites are measurable in blood and tissues and are excreted in urine with half-lives longer than ethanol itself.¹¹² Finding these non-oxidative metabolites, e.g., in urine taken at autopsy, is a strong indication that the deceased had consumed alcohol some time before death. The sensitivity of these markers compared with EtG and EtS remains to be established.

Another biochemical approach is based on the metabolic interaction between ethanol and the biogenic amine serotonin (Figure 5.3.1).¹¹² Without any consumption of alcohol, serotonin (5-hydroxytryptamine) undergoes oxidative deamination to 5-hydroxyindolealdehyde (5-HIALD).^{112–114} This short-lived intermediate is rapidly oxidized to 5-hydroxyindoleacetic acid (5-HIAA) and a very small fraction (~1%) is reduced to 5-hydroxytryptophol (5-HTOL). Formation of the carboxylic acid (5-HIAA) is the dominant reaction and the 5-HTOL/5-HIAA ratio in urine is normally very low (<15 nmol/μmol). However, after a person drinks alcohol the 5-HTOL/5-HIAA ratio increases appreciably owing to competitive inhibition for ALDH, which is now engaged in the metabolism of acetaldehyde derived from ethanol.^{112–114} Measuring the 5-HTOL/5-HIAA ratio in urine has therefore found applications in clinical medicine to disclose consumption of alcohol, e.g., in alcohol and drug abusers, who must refrain from drinking as part of their treatment.¹¹² The ratio of serotonin metabolites can also be used to differentiate between ante-mortem ingestion of ethanol and post-mortem microbial synthesis.^{113–115} Finding an elevated concentration

of ethanol in urine but with a 5-HTOL/5-HIAA ratio below 15 nmol/μmol strongly suggests that microbial synthesis of ethanol has occurred.^{115–117} However, the question of whether an elevated concentration of ethanol in a post-mortem specimen partly reflects microbial synthesis and partly ante-mortem ingestion cannot be resolved using these kinds of biochemical markers.

5.3.9 Sequestered Hematomas

That ethanol might be measured in sequestered hematomas was first suggested by Hirsch and Adelson,¹¹⁸ although they claimed no originality, explaining that it is one of the “tricks of the trade.” It has been most commonly applied to cases of head trauma with subdural or epidural hematomas,^{118–121} but also to intracerebral clots.^{122,123} Although primarily used for ethanol, any toxicant might be measured in the hematoma. From the accumulated case data (Table 5.3.2), it is clear that concentrations of ethanol in subdural hematomas may be markedly different from autopsy peripheral blood. In interpreting the significance of the results several possibilities should be considered. The hematoma may have developed rapidly at the time of injury, or it may have been delayed and not developed for some hours, or it may have evolved over a period of time as the result of continuous or intermittent bleeding. If the hematoma accumulates over a period of hours, then its ethanol content will reflect a changing blood ethanol concentration during that time. Furthermore, the hematoma might not be perfectly sequestered and ethanol may diffuse both out of it and into it. An animal model¹²¹ has provided good experimental evidence that the current approach to determination of ethanol in sequestered hematomas is well founded.

In cases of head trauma associated with subdural or extradural hematomas and with a prolonged survival time, the autopsy blood ethanol concentration may be very low or even zero whereas the ethanol concentration in the hematoma may be substantial, thus providing evidence that the deceased may have been intoxicated at the time of injury. In a study of 75 cases in which ethanol was measured in subdural hematomas and cardiac blood,¹¹⁹ the analysis provided useful new information only in those cases with survival times greater than 9 h since it was these cases in which the blood ethanol had diminished markedly or been fully metabolized. In another case series consisting of 15 fatalities from penetrating and nonpenetrating head injuries,¹²⁰ there was a pre-mortem blood ethanol measurement available. Findings in nonpenetrating injuries (Table 5.3.3) and penetrating injuries were similar in that concentrations of ethanol in intracranial hematoma did not accurately

Table 5.3.3 Ethanol in Ante-Mortem Blood and Sequestered Hematomas¹²⁰

Time (h)		Ethanol (mg/dL)		
Injury to Pre-Mortem Sample	Pre-Mortem Sample to Death	Pre-Mortem	Post-Mortem	SDH
1	21	535	0	170
3	7	486	130	190
5	8.5	183	0	90
3	41	161	0	40
1 1/2	4.5	164	70	110
2	18	93	0	120
1	25.5	240	0	110
1	58	101	0	40

Note: SDH = subdural hematoma.

reflect circulating blood concentrations at the time of injury. Therefore, quantitative interpretations must be cautious.

After suffering trauma, the development of an intracranial hemorrhage, either subdural or intracerebral, may be delayed. If the victim was intoxicated at the time of injury, then this delay may be sufficient to allow clearance of ethanol from the blood. The intracranial hematoma will then contain no ethanol despite the history of injury when intoxicated. This apparent conflict between the history of the circumstances of injury and the absence of ethanol in the hematoma has been used to provide corroboration that development of the hematoma had been delayed.¹²⁴

5.3.10 Alcoholic Ketoacidosis

Sudden death in a chronic alcoholic with a subsequent negative autopsy is a common problem. At autopsy such cases have only the stigmata of alcoholism, such as a fatty liver, and an inconsequential blood alcohol level. The mechanism behind these “fatty liver deaths” is obscure,¹²⁵ and recently the syndrome of alcoholic ketoacidosis (AKA) has been suggested as having a role.^{126,127} The clinical literature on AKA is scant, and probably belies the true frequency of the syndrome,^{128–135} but it does suggest that AKA is typically a relatively benign condition and only fatal when associated with some other disease process. The combination of starvation and alcohol abuse together precipitate the syndrome of AKA,¹²⁸ which is characterized by a metabolic acidosis, malnutrition, and binge drinking superimposed upon chronic alcohol abuse.¹³¹ The typical clinical picture is that of an alcohol debauch terminated by anorexia with cessation of both food and alcohol intake, and finally, a variable period of hyperemesis. By the time AKA develops there is no measurable blood alcohol. The common symptoms of nausea, vomiting, and abdominal pain are accompanied by few objective physical findings and mental status is usually normal or only slightly impaired, but severe obtundation or coma occasionally occurs.¹³²

Although the pathophysiology of AKA is complex, it seems that the pivotal variable is probably a relative deficiency of insulin. This results from starvation with consequent hepatic glycogen depletion, the inhibition of gluconeogenesis by an increased NADH/NAD⁺ ratio resulting from metabolism of alcohol, and extracellular fluid volume depletion with α -adrenergic inhibition of insulin secretion.¹³³ Individuals with higher insulin levels would probably present with the syndrome of alcohol-induced hypoglycemia without ketoacidosis. Possibly the major factor separating AKA from alcohol-induced hypoglycemia is the dehydration and the starvation-induced α -adrenergic inhibition of insulin secretion in the former.

Extremely high free fatty acid levels in blood, ranging from 1800 to 3800 μ Eq/L have been a consistent finding in clinical cases of AKA.^{128,129} Beta-oxidation of these fatty acids generates acetyl-CoA, which is the precursor of ketones. Two critical enzymes in the ketogenesis pathway to acetoacetate are found in liver mitochondria only,¹³⁰ so that the liver is the only appreciable site

of ketone body production. Excess acetoacetate in liver is converted into β -hydroxybutyrate and extrahepatic tissues can convert β -hydroxybutyrate back into acetoacetate and utilize both of these ketone bodies as respiratory substrates. Acetone is thought to be the product of a non-enzymatic decarboxylation of acetoacetate. Acetone production is therefore a function of the level of acetoacetate and the duration of its elevation, so that the presence of acetone is indicative of a sustained severe ketoacidosis.¹³⁴ However, the extent, if any, of post-mortem conversion of acetoacetate to acetone is not known and it is advisable and convenient to make a combined analysis of these two ketones in autopsy samples.¹²⁷ For convenience, the term “ketone bodies” is used to include only acetone, acetoacetate, and β -hydroxybutyrate. While this terminology is convenient because all three compounds are metabolically related, it is inaccurate because it excludes other biologically important ketones, e.g., pyruvate, but includes β -hydroxybutyrate, which does not have a ketone structure, although it is part of ketone metabolism.

The biochemical hallmark of AKA is ketoacidosis without marked hyperglycemia,¹³² while by contrast diabetic ketoacidosis is defined by the triad of hyperglycemia, acidosis, and ketosis. In AKA the ratio of serum β -hydroxybutyrate to acetoacetate, which is normally 1:1, is increased to between 2:1 and 9:1, a ratio higher than that generally found in diabetic ketoacidosis.¹³⁵ The clinical diagnosis of AKA is hampered because the nitroprusside test (Acetest) for ketones in the urine is sensitive to acetoacetate but not to β -hydroxybutyrate.¹²⁹ In fasting subjects the concentration of acetoacetate in plasma might range up to 0.23 mmol/L, and that of β -hydroxybutyrate up to 0.65 mmol/L. In comparison, in AKA the corresponding concentrations of acetoacetate have range up to 7.5 mmol/L and of β -hydroxybutyrate up to 20.5 mmol/L.¹²⁷ In one autopsy study,¹²⁶ total ketones (mmol/L) in 71 non-alcoholics were as follows: vitreous 0.19 to 3.35, median 0.49; pericardial fluid 0.02 to 1.54, median 0.35; and femoral blood 0.23 to 8.08, median 1.00. The significantly high levels found in this autopsy series likely reflect deaths from chronic disease or prolonged agonal periods. Among 22 alcoholics, 18 had ketone levels not statistically different from non-alcoholics but there were 4 with femoral blood total ketone levels of 129.9 (also diabetic), 39.4 (no anatomical cause of death), 38.5 (suicidal hanging), and 18.6 (hypothermia), suggesting that while alcoholic ketoacidosis may be a previously overlooked potential cause of death, interpretation must be guarded and made within the total case context. This is in keeping with the clinical consensus that AKA is fatal only when associated with some other illness.

In the present state of knowledge it is uncertain whether AKA alone is sufficient to account for death, but it seems that very high levels of ketones (>10 mmol/L in femoral blood and >5 mmol/L in vitreous) are indicative of profound AKA, and these values can be expected in about 10% of all alcoholics subjected to a medicolegal autopsy. Both vitreous and pericardial fluid ketone levels are lower than those in post-mortem blood, possibly because they are less affected by any agonal or post-mortem changes. Alcoholic ketoacidosis can be diagnosed at autopsy by measurement of total ketone bodies (acetone, acetoacetate, and β -hydroxybutyrate) in vitreous humor, pericardial fluid, or peripheral blood. Finding significantly elevated levels is associated with a typical history of an alcoholic binge followed by a day or more of anorexia, and consequently an insignificant BAC. In alcoholics in whom the autopsy is negative (so-called fatty liver deaths), AKA may be an explanation for sudden death as a result of profound acidosis, with a critical fall in blood pH to around 7.0, precipitating vascular collapse.

5.3.11 Post-Mortem Markers for Alcohol Abuse

The prevalence of alcoholism in the forensic autopsy population varies between jurisdictions but can be as high as 10% or more. Poor hygiene and multiple bruises of different ages are more common in chronic alcoholics than in the general forensic autopsy population, and raise the index of suspicion in an individual case. The traditional method of diagnosing chronic alcoholism post-mortem is to evaluate the BAC and liver histology in the light of the available medical history. However, the presence of alcohol in the blood merely indicates alcohol ingestion prior to death

and almost half of all alcoholics die with a zero BAC. Also, the pathological features of alcoholic liver disease are relatively nonspecific and the extent of liver disease in many alcoholics is no worse than in the general forensic autopsy population.

The spectrum of alcoholic liver disease includes hepatomegaly, steatosis with or without lipogranulomas, alcoholic hepatitis, and cirrhosis.¹³⁶ This complete spectrum, including alcoholic-type hepatitis, can be perfectly mimicked by a few non-alcohol-related conditions such as obesity with or without dieting, jejuno-ileal bypass for obesity, diabetes mellitus, and perhexilline maleate toxicity. Hepatic steatosis is the most common form of alcoholic liver disease seen at necropsy, and significant steatosis may be induced by the amounts of alcohol consumed by many social drinkers. Following the withdrawal of alcohol, the mobilization of this accumulated fat begins in 1 to 2 days and is complete in 4 to 6 weeks even in severe cases. While hepatic steatosis is potentially reversible, alcoholic hepatitis is thought by some to represent the point of no return within the spectrum, for once this stage is reached the disorder tends to progress to cirrhosis. Even so, a person with alcoholic hepatitis may be symptom-free and performing normal social functions. In general, there is not always a good correlation between symptoms and morphological findings in alcoholic hepatitis. Histologically, alcoholic hepatitis is characterized by liver cell necrosis with a predominantly neutrophil polymorph reaction and peri-cellular fibrosis. The hepatitis is mainly centrilobular in distribution and classically associated with the presence of Mallory's hyaline. More than half of all cases of cirrhosis coming to autopsy are the result of alcohol abuse. The classical alcoholic cirrhosis is micronodular and fatty, but this is not necessarily so since it may not be fatty and may evolve into a macronodular cirrhosis. Persons abusing alcohol frequently abuse other drugs and may develop drug-related hepatotoxicity, in particular late acetaminophen (paracetamol) toxicity from excessive, but not suicidal, doses of this antipyretic drug.

The search for a corroborative post-mortem biochemical marker for chronic alcoholism has taken as a starting point those clinical studies on the value of biochemical markers of alcoholism in the living. The serum enzyme γ -glutamyltransferase (GGT) is one of the most frequently used clinical markers and has a reported sensitivity of 39 to 87% but a specificity of only 11 to 50%.¹³⁷ This poor specificity is mainly the result of interference by various hepatic and other diseases, and drug therapy. At autopsy the difficulties are greater because GGT is subject to significant post-mortem changes. GGT levels in right heart blood may be two to eight times greater than in femoral venous blood owing to post-mortem diffusion of GGT from the liver. Furthermore, post-mortem hemolysis interferes with some quantitative enzymatic GGT methods. More recently, carbohydrate-deficient transferrin (CDT) has been used as a clinical marker of alcoholism, offering 83 to 90% sensitivity and 99% specificity.¹³⁷ CDT is thought to become elevated at the threshold of hazardous drinking, which is generally accepted as being 50 to 80 g/day. An assessment of the value of CDT in diagnosing chronic alcoholism at autopsy concluded that it might have a sensitivity of 70% and a specificity of 85% if the cut-off value for the diagnosis of alcohol abuse post-mortem was raised above the accepted clinical cut-off value.¹³⁸ This suggests that both CDT and GGT are likely to be subject to post-mortem changes.

Trace amounts of methanol (less than 1.0 mg/L) are produced in the body in the course of intermediary metabolism and the endogenous levels increase during a period of heavy drinking. Ingestion of methanol as a congener in various alcohol beverages adds to this accumulation.¹³⁹ When alcoholics consume alcohol over a period of several days or weeks reaching blood ethanol concentrations of 150 to 450 mg/dL, then the methanol levels in blood and urine progressively increase to 20 to 40 mg/L. The elimination of methanol lags behind ethanol by 12 to 24 h and follows approximately the same time course as ethanol withdrawal symptoms leading to speculation on the role of methanol and/or its metabolites in alcohol withdrawal and hangover.¹³⁹ Below a blood ethanol concentration of about 10 mg/dL, hepatic ADH is no longer saturated with its preferred substrate and the metabolism of methanol can therefore commence. At this low concentration the elimination of ethanol follows first-order kinetics with a half life of 15 min.¹³⁹ The half-life of methanol, however, is about ten times longer. As a result elevated concentrations of methanol will

persist in blood for about 10 h after ethanol has reached endogenous levels and can serve as a marker of recent heavy drinking.¹³⁹

Blood methanol levels in 24 teetotalers ranged from 0.1 to 0.8 mg/L with a mean of 0.44 mg/L so that these levels can be regarded as physiological. By contrast, blood methanol concentrations in samples taken on admission of 20 chronic alcoholics to hospital ranged from 0.22 to 20.1 mg/L.¹⁴⁰ The general extent to which methanol may accumulate in the blood of chronic alcoholics can be gauged from a study of ethanol and methanol in blood samples from 519 drunk-driving suspects.¹³⁹ The concentration of ethanol ranged from 0.01 to 3.52 mg/g and the concentration of methanol in the same sample ranged from 1 to 23 mg/L with a mean of 7.3 (SD 3.6) and a positively skewed distribution. By contrast, in 15 fatalities following hospital admission for methanol poisoning the concentrations of methanol in post-mortem blood from the heart ranged from 23 to 268 mg/dL.¹⁴¹

5.3.12 Methanol

Methanol (wood alcohol) is used as antifreeze, photocopier developer, a paint remover, a solvent in varnishes, a denaturant of ethanol, and is readily available as methylated spirit. It may be used also as a substitute for ethanol by alcoholics.¹⁴² The distribution of methanol in body fluids (including vitreous humor) and tissues was reported as similar to that of ethanol, but there may be preferential concentration in liver and kidney.^{143,144} The lethal dose of methanol in humans shows pronounced individual differences ranging from 15 to 500 mL. Clusters of poisonings are seen secondary to consumption of adulterated beverages.^{141,145,146}

Acute methanol poisoning produces a distinct clinical picture with a latent period of several hours to days between consumption and the appearance of first symptoms. A combination of blurred vision with abdominal pain and vomiting is found in the majority of victims within the first 24 h after presentation. Visual disturbances, pancreatitis, metabolic acidosis, and diffuse encephalopathy may be seen in severe cases.¹⁴⁵ The characteristic delay between ingestion and onset of symptoms is thought to reflect the delayed appearance of metabolites (formaldehyde and formic acid), which are more toxic than methanol itself.

Methanol poisoning is characterized by a metabolic acidosis with an elevated anion gap. The serum anion gap is defined as (sodium + potassium) to (bicarbonate + chloride), and represents the difference in unmeasured cations and unmeasured anions, which includes organic acids. Both formic acid, produced by methanol catabolism, and lactic acid, resulting from disturbed cellular metabolism, are responsible for the metabolic acidosis.¹⁴⁷ The severity of the poisoning correlates with the degree of metabolic acidosis more closely than with the blood concentration of methanol.¹⁴⁸ Measuring formic acid concentrations may be of some value in assessing methanol poisoning. Reported formic acid levels in two methanol fatalities were 32 and 23 mg/dL in blood and 227 and 47 mg/dL in urine.¹⁴⁹ One well-documented outbreak of methanol poisoning¹⁵⁰ involved 59 people, 8 of whom died outside hospital while 51 were hospitalized, and of these a further 9 died in hospital, 5 survived with sequelae, and 1 died a year later of cerebral sequelae. In the 51 hospitalized victims, who had a median age of 53 years, the serum concentration of methanol (range 10 to 470 mg/dL, median 80 mg/dL) proved a poor predictor of survival or visual sequelae. Respiratory arrest or coma on hospital admission was associated with 75 and 67% mortality, respectively. Overall, prognosis was closely correlated with the degree of metabolic acidosis, so that a fatal outcome was associated with a pH < 6.9 and base deficit > 28 mmol/L, with an inadequate ability to compensate for the metabolic acidosis by hyperventilation being reflected in an increased blood pCO₂.

Methanol poisoning has a high mortality mainly because of delay in diagnosis and treatment.¹⁵⁰ The standard treatment includes the competitive inhibition of methanol oxidation by the intravenous administration of ethanol, thus preventing the formation of toxic metabolites, formaldehyde and formic acid. Both methanol and ethanol are substrates for hepatic ADH, although the affinity of the enzyme is much higher for ethanol than for methanol by about 10:1.¹⁵¹ Consequently, the biotransformation of methanol into its toxic metabolites can be blocked by the administration of

ethanol.¹⁵² One disadvantage of ethanol is that it exerts its own depressant effect on the central nervous system at the steady-state concentration of 100 to 120 mg/dL in blood, which must be maintained for many hours.^{152,153} A more modern, and expensive, antidote for methanol poisoning is fomepizole (4-methyl pyrazole or Antizol®), which also acts as a competitive inhibitor of alcohol dehydrogenase.^{154,155} This drug is preferred to ethanol for treating children and adults with known liver dysfunction.¹⁵⁶ During fomepizole treatment, the concentration of formate in blood may be a better prognostic indicator than the methanol concentration.¹⁵⁷

5.3.13 Isopropyl Alcohol

Isopropyl alcohol (isopropanol) is used as a substitute for ethanol in many industrial processes and in home cleaning products, antifreeze, and skin lotions. A 70% solution is sold as “rubbing alcohol” and may be applied to the skin and then allowed to evaporate, as a means of reducing body temperature in a person with fever. Isopropanol has a characteristic odor and a slightly bitter taste. Although much less dangerous than methanol, deaths have been reported following accidental ingestion of isopropanol, e.g., in alcoholics who use it as an ethanol substitute.¹⁵⁸ Fatalities may occur rapidly as a result of central nervous system depression or may be delayed, when the presence or absence of shock with hypotension is the most important single prognostic factor.

Isopropyl alcohol has an apparent volume of distribution of 0.6 to 0.7 L/kg, being similar to that of ethanol and with distribution complete within about 2 h.^{159,160} Elimination most closely approximates first-order kinetics although this is not well defined ($t_{1/2}$ = 4 to 6 h).¹⁶¹ This secondary alcohol is metabolized to acetone, predominantly by liver alcohol dehydrogenase, and approximately 80% is excreted as acetone in the urine with 20% excreted unchanged.^{161,162} The acetone causes a sweet ketonic odor on the breath. The elimination of both isopropanol and its major metabolite acetone obeyed apparent first-order kinetics with half-lives of 6.4 and 22.4 h, respectively, in a 46-year-old non-alcoholic female with initial serum isopropanol and acetone concentrations of 200 and 12 mg/dL, respectively.¹⁶¹

In a review of isopropanol deaths, 31 were attributed to isopropanol poisoning alone, and the blood isopropanol concentrations ranged from 10 to 250 mg/dL, mean 140 mg/dL, and acetone ranged from 40 to 300 mg/dL, mean 170 mg/dL.¹⁶³ Four cases with low blood isopropanol levels (10 to 30 mg/dL) had very high acetone levels (110 to 200 mg/dL). For this reason both acetone and isopropanol should be measured in suspected cases of isopropanol poisoning.

High blood levels of acetone may be found in diabetes mellitus and starvation ketosis, which opens the possibility that ADH might reduce acetone to isopropyl alcohol. This is the suggested explanation for the detection of isopropyl alcohol in the blood of persons not thought to have ingested this compound. In 27 such fatalities blood isopropyl alcohol ranged from less than 10 to 44 mg/dL with a mean of 14 mg/dL, and in only 3 cases was the concentration greater than 20 mg/dL. Acetone levels ranged up to 56 mg/dL and in no individual case did the combined isopropanol and acetone levels come close to those seen in fatal isopropyl alcohol poisoning.¹⁶⁴

5.3.14 Concluding Remarks

Blood ethanol concentration can be expected to be positive in around one half of all unnatural deaths so that routine screening of such deaths for ethanol is highly desirable. For natural deaths as a whole, the return of positives is not sufficiently high to justify screening, unless there is a history of chronic alcoholism or of recent alcohol ingestion. The autopsy blood sample should never be obtained from the heart, aorta, or other large vessels of the chest or abdomen or from blood permitted to pool at autopsy in the pericardial sac, pleural cavities, or abdominal cavity. If by mischance such a specimen is the only one available, then its provenance should be clearly declared and taken into account in the interpretation of the analytical results. Blind needle puncture of the chest to obtain a “cardiac” blood sample or a so-called “subclavian stab” is not recommended

because at best it produces a chest cavity blood sample of unknown origin and at worst a contaminated sample. The most appropriate routine autopsy blood sample for ethanol analyses, as well as other drug analyses, is one obtained from either the femoral vein or the external iliac vein using a needle and syringe after clamping or tying off the vessel proximally. The sample should be obtained early in the autopsy and prior to evisceration. Samples of vitreous humor and urine, if the latter is available, should also be taken. The interpretation of the significance of the analytical results of these specimens must, of necessity, take into account the autopsy findings, circumstances of death, and recent history of the decedent. To attempt to interpret the significance of an alcohol level in an isolated autopsy blood sample without additional information is to invite a medicolegal disaster.

5.4 RECENT ADVANCES IN BIOCHEMICAL TESTS FOR ACUTE AND CHRONIC ALCOHOL CONSUMPTION

Anders Helander, Ph.D.¹ and Alan Wayne Jones, D.Sc.²

¹ Department of Clinical Neuroscience, Karolinska Institute and Karolinska University Hospital, Stockholm, Sweden

² Department of Forensic Toxicology, University Hospital, Linköping, Sweden

5.4.1 Introduction

Most people enjoy a drink and, for the vast majority of individuals, alcohol is a harmless, socially accepted recreational drug.¹ However, for about 10% of the population, especially among men, moderate drinking eventually leads to alcohol abuse and dependence with serious consequences for the individual and society.^{2,3} Overconsumption of alcohol is a major public health hazard and a cause of premature death and morbidity.^{4,5} Binge drinking, which is usually defined as consumption of five or more drinks on one occasion, is often associated with acute intoxication, hooliganism, drunk driving, and other deviant behavior with negative consequences for the person's family and friends.^{6,7}

Statistics show that alcohol consumption is increasing worldwide in both sexes and this legal drug creates enormous costs for society in terms of treatment and rehabilitation of those who abuse alcohol.^{8–10} Early recognition of problem drinkers in the society is therefore important to ensure adequate treatment strategies.¹¹ According to the American Medical Association, the difference between moderate use, abuse, and alcohol dependence (“alcoholism”) are summarized as follows:

1. The consumption of alcohol in amounts considered harmless to health entails drinking at most one to two drinks per day (~10 to 20 g ethanol), and never first thing in the morning or on an empty stomach and the resulting blood alcohol concentration (BAC) should not exceed 0.2 g/L (0.02 g%) on any drinking occasion.
2. Abuse of alcohol is a pattern of drinking that is accompanied by one or more of the following problems: (a) failure to fulfill major work, school, or home responsibilities because of drinking, (b) drinking in situations that are physically dangerous, such as driving a car or operating machinery, (c) recurring alcohol-related legal problems, such as being arrested for driving under the influence of alcohol or for physically hurting someone while drunk, and (d) having social or relationship problems that are caused by or worsened by the effects of alcohol.
3. Alcohol dependence is a more severe pattern of drinking that includes the problems of alcohol abuse and persistent drinking in spite of obvious physical, mental, and social problems caused by alcohol. Also typical are (a) loss of control and inability to stop drinking once begun, (b) withdrawal symptoms associated with stopping drinking such as nausea, sweating, shakiness, and anxiety, and (c) tolerance to alcohol, needing increased amounts of alcohol in order to feel drunk.

Denial of drinking practices has always been a major stumbling block in the effective treatment of alcohol abuse and dependence.¹² Drinking histories are notoriously unreliable and this tends to complicate early detection and treatment of the underlying alcohol problem.^{13,14} Much research effort has therefore focused on developing more objective ways to disclose excessive drinking, so that help

Table 5.4.1 Examples of Biochemical Markers of Alcohol Use and Abuse, and Possible Predisposition to Alcohol Dependence

Classification	Examples of Biochemical Markers
Acute Markers	Ethanol 5-Hydroxytryptophol (5HTOL) Ethyl glucuronide (EtG) Ethyl sulfate (EtS) Fatty-acid ethyl esters (FAEE)
State Markers	γ -Glutamyl transferase (GGT) Alanine aminotransferase (ALT) Aspartate aminotransferase (AST) Mean corpuscular volume (MCV) Carbohydrate-deficient transferrin (CDT) Phosphatidylethanol (PEth)
Trait Markers	Monoamine oxidase (MAO) Adenylyl cyclase (AC) Neuropeptide Y (NPY)

can be given to those at risk of becoming dependent on alcohol.¹⁵ In this connection, the use of various clinical laboratory tests is a useful complement to self-report questionnaires, such as the MAST and CAGE,^{16,17} which are intended to divulge the quantity and frequency of alcohol consumption as well as various social-medical problems associated with alcohol abuse and dependence.

Accordingly, a multitude of biochemical markers have been developed to provide more objective ways of diagnosing overconsumption of alcohol and risk for alcohol-induced organ and tissue damage.^{18–21} The liver is particularly vulnerable to heavy drinking and damage to liver cells is often reflected in an increased activity of various enzymes in the bloodstream, such as γ -glutamyl transferase (GGT) and alanine and aspartate aminotransferase (ALT and AST).^{22,23} However, it seems that some individuals can drink excessively for months or years without displaying abnormal results with this kind of biochemical test, which implies a low *sensitivity* for detecting hazardous drinking. By contrast, some biological markers yield positive results in people suffering from non-alcohol-related liver problems, or after taking certain kinds of medication, which implies a low *specificity* for detecting alcohol abuse.

Nevertheless, interest in the use of biochemical tests or biomarkers for screening those individuals at most risk of developing problems with alcohol consumption has expanded greatly.^{21,24,25} Besides many applications in clinical practice, such as in the rehabilitation of alcoholics and in drug-abuse treatment programs,²⁶ biochemical markers have found uses in occupational medicine,^{27,28} forensic science,^{29–32} and experimental alcohol research.^{33,34} In general, three major classes of biochemical markers have been distinguished (examples are given in Table 5.4.1):

1. Tests sufficiently sensitive to detect even a single intake of alcohol, known as *acute markers* or *relapse markers*.
2. Tests that indicate disturbed metabolic processes or malfunctioning of body organs and/or tissue damage caused by long-term exposure to alcohol. This is reflected in altered hematological and/or biochemical parameters in blood or other body fluids. Such tests are referred to as *state markers* of hazardous alcohol consumption.
3. Tests that indicate whether a person carries a genetic predisposition for heavy drinking, abuse of alcohol, and development of alcohol dependence. Such tests are known as *trait markers* and often rely on identifying an abnormal enzyme or receptor pattern at the molecular level. Those prone to develop into heavy drinkers exhibit at an early age marked personality disorders, including sensation-seeking behavior, binge drinking, and abuse of other drugs.

In this chapter, we present an update of research dealing with laboratory markers for both acute and chronic drinking. The advantages and limitations of various laboratory tests are discussed and suggestions are made for their rational use in clinical and forensic medicine.

5.4.2 Diagnostic Sensitivity and Specificity

Biochemical markers are usually evaluated in terms of diagnostic sensitivity and specificity. *Sensitivity* refers to the ability of a test to detect the presence of the trait in question, whereas *specificity* refers to its ability to exclude individuals without the trait. Consequently, a marker with high sensitivity yields relatively few false negative results and one with high specificity gives few false positives. The ideal marker should, of course, be both 100% sensitive and specific, but this is never achieved because reference ranges for normal and abnormal values always tend to overlap. Instead, a cutoff, or threshold limit, is established for what is considered normal. These limits are usually determined empirically as the mean plus or minus two standard deviations (SD) of the test results for a healthy control population. Accordingly, 2.5% of individuals will be above the upper limit and 2.5% below the lower limit and the test specificity will always be less than 100%.

To obtain a sufficiently high specificity for routine purposes, the sensitivity of some markers has to be gradually reduced. On the other hand, most tests aimed at indicating liver damage caused by prolonged alcohol abuse often suffer from low specificity, because many liver diseases have non-alcoholic origin. So-called receiver-operating characteristic (ROC) curves are widely used for evaluating utility of biochemical markers and for comparing different analytical methods.³⁵ ROC curves are graphic illustrations created by plotting the relation between sensitivity (i.e., the percentage of true positives) against 1-specificity (i.e., the percentage of false positives) at different cutoff limits between normal and abnormal values.³⁶

Most studies aimed at evaluating the sensitivity and specificity of alcohol biomarkers rely heavily on patient self-reports about drinking as the gold standard. However, considering that many patients fail to provide an accurate history of their true alcohol consumption, this creates a validity problem. Hence, besides the use of sensitive and specific markers of excessive alcohol consumption, there is also a need to develop and evaluate laboratory tests to monitor recent alcohol consumption in a more objective way.

5.4.3 Tests for Acute Alcohol Ingestion

5.4.3.1 Measuring Ethanol in Body Fluids and Breath

Ethanol and water mix together in all proportions and, after drinking alcoholic beverages, the ethanol distributes into all body fluids and tissues in proportion to the amount of water in these fluids and tissues. The body water in men makes up about 60% of their body weight and the corresponding figure for women is ~50%, although there are large inter-individual differences in these average figures, depending on age and, especially, the amount of adipose tissue. Accordingly, the most specific and direct way to demonstrate that a person has been drinking alcohol is to analyze a sample of blood, breath, urine, or saliva. However, because concentrations of ethanol in these body fluids decrease over time, owing to metabolism and excretion processes, the time frame for positive identification is rather limited.^{37,38}

The smell of alcohol on the breath is perhaps the oldest and most obvious indication that a person has been drinking. But many alcoholics use breath fresheners or can regulate their intake so that the BAC is low or zero when they are examined by a physician.³⁹ A more objective way to disclose recent alcohol consumption is to measure the concentration of ethanol in the exhaled air. Several kinds of handheld breath alcohol analyzers are available for this purpose, such as Alcolmeter SD-400, AlcoSensor IV, or Alcotest 4010. The ethanol in a sample of breath is oxidized with an electrochemical sensor and the magnitude of the response is directly proportional to the concentration of ethanol present.⁴⁰ Studies have shown that these breath analyzers are accurate, precise, and selective for their intended purpose. Endogenous breath volatiles, such as acetone, are not oxidized under the same conditions and therefore does not interfere with the selectivity of the test for ethanol.

Breath alcohol concentration (BrAC) tests should become a standard procedure, if a patient is required to refrain from drinking as part of rehabilitation or treatment or because of workplace regulations concerning the use of alcohol.⁴¹ However, a positive breath test needs to be confirmed by making a repeat test not less than 15 min later, to rule out the presence of ethanol in the mouth from recent drinking. Most of the currently available handheld breath alcohol analyzers have an analytical sensitivity of about 0.05 mg ethanol per liter breath, which corresponds to a blood ethanol equivalent of 10 mg/dL (~2.2 mmol/L). The result of a breath alcohol test appears immediately after capturing the sample and results are reported in units of g/210 L (U.S.) or mg/L (Sweden) or µg/100 mL (U.K.). Alternatively, the result of the test is translated into the presumed coexisting BAC and for this application the breath alcohol instrument is precalibrated with a blood/breath conversion factor, usually assumed to be 2100:1 or 2300:1. Careful control of calibration and maintenance of these breath test instruments is important to ensure obtaining valid and reliable results.

Measuring the concentration of ethanol in whole blood or plasma/serum will also provide reliable information about recent drinking. However, obtaining a sample of blood is an invasive procedure and the concentration of ethanol, if any, is not obtained immediately after sampling. The analysis of ethanol in blood or plasma is therefore less practical than breath testing, for clinical purposes, as a rapid screening test for recent drinking. The sensitivity of methods for blood alcohol analysis (e.g., gas chromatography; GC) is higher than breath test instruments and a BAC as low as 1 mg/dL can be measured. However, for clinical applications, it is wise to use a higher cutoff (i.e., decision limit) such as 5 or 10 mg/dL, to avoid discussions and debate that the ethanol came from some dietary constituent, such as fresh fruits or soft drinks.

After absorption and distribution of ethanol in body fluids and tissues is complete, there is a close correlation between the concentrations in saliva, blood, and urine. The equilibration of ethanol between blood and saliva is fairly rapid, which makes saliva sampling more suitable than urine for clinical purposes.^{42,43} A number of devices have been developed for measuring ethanol in saliva and these have proved useful for alcohol screening purposes in clinical settings. A saliva-test device called QED has been evaluated extensively and gives on-the-spot results as to whether a person has consumed alcohol. The QED test incorporates alcohol dehydrogenase (ADH) to oxidize ethanol with the coenzyme NAD⁺ at pH 8.6. Ethanol is converted into acetaldehyde and the NADH is formed in direct proportion to the concentration of ethanol present. The acetaldehyde is trapped with semicarbazide to drive the reaction to completion. The NADH is then re-oxidized to produce a colored end product, by reaction with the enzyme diaphorase and a tetrazolium salt incorporated on a solid phase support. The length of the resulting blue-colored bar is directly proportional to the concentration of ethanol in the saliva sample and permits a direct readout of the test result about 1 min later. Saliva alcohol concentrations determined with QED agreed well with BAC and BrAC in controlled drinking experiments.^{44,45}

Numerous studies have compared concentrations of ethanol in blood and urine sampled at various times after end of drinking.^{46,47} In the post-absorptive phase, the urine-alcohol concentration (UAC) and the BAC are highly correlated ($r > 0.95$). Some have tried to estimate BAC indirectly from UAC, assuming a population average UAC/BAC, such as 1.3:1. However, there are large inter- and intra-individual variations in this relationship, which means that the estimated BAC will have a considerable uncertainty in any individual case.

One expects to find a higher concentration of ethanol in urine compared with blood, because of the difference in water content of these body fluids, namely, 100% vs. 80%. This suggests a UAC/BAC ratio of 1.25:1 for freshly produced urine. In reality, however, the UAC/BAC ratio also depends on the time after drinking, when the bladder was last voided, and how frequently the person urinates. Urine is stored but not metabolized in the bladder, whereas the BAC changes continuously, depending on the stage of metabolism and the rate of hepatic oxidation. Shortly after drinking during the absorption phase, the UAC and BAC are not well correlated, whereas in the post-peak phase, when BAC is decreasing at a constant rate of about 15 mg/dL/h, a good correlation exists between BAC and UAC.

Figure 5.4.1 Mean concentration-time profiles of ethanol in blood and urine in 30 healthy men who drank 0.85 g/kg body weight after an overnight fast. The bladder was emptied before the start of drinking and alcohol was taken in the form of neat whisky.

The average curves for venous blood and urine concentration–time profiles of ethanol are compared in Figure 5.4.1. One notes that UAC and BAC curves are shifted in time, as a consequence of the time-lag between ethanol being absorbed into the bloodstream, reaching the kidney, and passing into the glomerular filtrate, and its storage in the bladder until voided. Shortly after the end of drinking, the UAC is less than the BAC ($\text{UAC/BAC} < 1.0$). After the peak BAC is reached, the two curves cross and the UAC has a higher C_{max} compared with the BAC. In the post-absorptive phase, the UAC is always higher than the corresponding BAC by a factor of 1.3 to 1.4. Note that the UAC reflects the average BAC prevailing during the time that urine was produced and stored in the bladder since the previous void. The UAC in a random void does not reflect the BAC at the time of emptying the bladder and, in this respect, is less useful than blood, saliva, or breath as a test of alcohol influence. Instead, the UAC reflects the BAC during production and storage of urine in the bladder. The UAC remains elevated for about 1 h after the BAC has already reached zero. Accordingly, the first morning void after an evening's drinking might be positive for ethanol, although the concentrations in blood or breath have already reached zero.⁴⁸ This relationship suggests that the BAC has reached zero sometime during the night and any ethanol already in the urine gets diluted with ethanol-free urine produced after complete metabolism of the alcohol consumed. Metabolism of ethanol does not occur in the urinary bladder, and back-diffusion of ethanol into the bloodstream is negligible, owing to the limited blood circulation.

Small quantities of ethanol are excreted through the skin by passive diffusion and also secreted through the sweat glands. The transdermal elimination of ethanol corresponds to about 0.5 to 1% of the dose ingested.⁴⁹ However, this route of excretion has found applications in clinical medicine, as a way to monitor alcohol consumption over periods of several weeks or months. This approach might be useful to control if alcoholics and others manage to remain abstinent, and has led to the introduction of a procedure known as transdermal dosimeter or, more simply, the sweat-patch test.^{50,51} Although the first attempts to monitor alcohol consumption in this way were not very successful, owing to technical difficulties with the equipment used for collecting sweat, the procedures are now much improved and can be used to analyze other drugs of abuse as well.^{52,53} The test person wears a tamper-proof and water-proof pad, positioned on an arm or leg, and the low-molecular substances that pass through the skin are collected during the time the patch remains intact. Ethanol and other volatiles are extracted with water and the concentration determined provides a cumulative index of alcohol exposure. The ethanol collected in the cotton pad can be determined in a number of ways, such as by extraction with water and GC analysis or by headspace

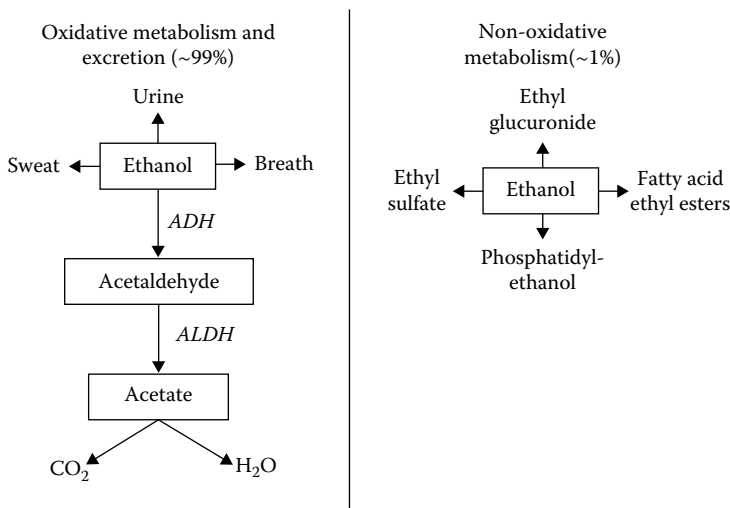

Figure 5.4.2 Fate of alcohol in the body illustrating both the oxidative and non-oxidative pathways of ethanol metabolism.

vapor analysis with a handheld electrochemical sensor, which was originally designed for breath alcohol testing.⁵⁴ A miniaturized electronic device for continuous sampling and monitoring of transcutaneous ethanol has recently been introduced.^{55,56}

5.4.3.2 Metabolism of Ethanol

The disposition and fate of ethanol in the body has been studied extensively since the 1930s and our knowledge about this legal drug exceeds that of other abused substances. Ethanol is cleared from the bloodstream by both oxidative and non-oxidative metabolic pathways (Figure 5.4.2).

The minor non-oxidative pathway of alcohol metabolism has received considerable research interest since the first edition of this book appeared and this topic is covered later in this chapter. The main alcohol-metabolizing enzymes are located in the liver, the kidney, and the gastric mucosa. The bulk of the alcohol a person consumes undergoes hepatic metabolism by the action of Class I ADH, which exists in various molecular forms, so-called isozymes. Ethanol is metabolized in a two-stage process, first to acetaldehyde and this primary metabolite is rapidly converted to acetate (acetic acid) by the action of low K_m aldehyde dehydrogenase (ALDH2) located in the mitochondria. The end products of the oxidation of ethanol are carbon dioxide and water (see Figure 5.4.2).

Hepatic ADH is not specific for oxidation of ethanol, and other aliphatic alcohols, if present in the blood, as well as a number of endogenous substances (e.g., prostaglandins and hydroxysteroids), also serve as substrates. The substrate specificity of ADH toward aliphatic alcohols differs widely, and the rate of oxidation of methanol is considerably slower than that of ethanol by a factor of about 10:1.⁵⁷ The biotransformation of ethanol and methanol and the various metabolic products formed are compared in Figure 5.4.3.

Raised concentrations of the intermediary products of ethanol oxidation have been proposed as a way to test for recent drinking.⁵⁶ However, measuring acetaldehyde is not very practical, because of the extremely low concentrations present (<1% of the ethanol concentration), and also the fact that the necessary analytical procedures are much more challenging than those for the analysis of ethanol.⁵⁸ Acetaldehyde is rapidly converted to acetate, and the concentration of free acetaldehyde in peripheral venous plasma is further reduced owing to a more or less specific binding to various endogenous molecules such as proteins (see also Section 5.4.4.6). An additional problem arises if the blood contains ethanol, because acetaldehyde is formed after sampling resulting in

Figure 5.4.3 Schematic diagram comparing the metabolism of ethanol and methanol via the alcohol dehydrogenase pathway: NAD⁺ = oxidized form of the coenzyme nicotinamide adenine dinucleotide; NADH = reduced form of the coenzyme. The various isozymes of alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH) are indicated.

falsely high results.^{58,59} Measuring acetaldehyde in breath instead of blood has been suggested as an alternative approach, although even breath testing is not without its problems.⁶⁰

The concentration of acetate in blood depends on the rate of ethanol oxidation and utilization of the acetate formed by peripheral tissues. The blood acetate concentration appears to be independent of the blood-ethanol concentration, and instead increases with the development of metabolic tolerance to alcohol (i.e., rate of ethanol elimination).^{61,62} Measuring blood acetate was suggested as a marker of chronic abuse of alcohol,^{63,64} and the sensitivity and specificity of this test was significantly higher than for GGT.⁶³ It should be emphasized, however, that blood-acetate remains elevated only as long as ethanol is being metabolized and, moreover, the rate of ethanol metabolism exhibits large inter-individual variations even in moderate drinkers.

5.4.3.3 Analysis of Methanol in Body Fluids

Ethanol and methanol are examples of endogenous alcohols and are normally present in biological specimens, albeit at extremely low concentrations (<1 mg/L). Moreover, trace quantities of the free alcohols or their esters might be ingested with certain foodstuffs or might be contained in soft drinks, such as fruit juices and sodas, or they could be formed by fermentation of dietary carbohydrates through the action of microorganisms inhabiting the gut.^{65–68}

During the end stages of carbohydrate metabolism, trace amounts of acetaldehyde are produced from pyruvate and, after reduction via the ADH/NAD⁺ pathway, lead to small amounts of ethanol being present in body fluids.⁶⁹ The trace amounts of the endogenous alcohols produced in the gut are rapidly cleared from the portal venous blood, as it passes through the liver for the first time. The existence of an effective first-pass metabolism ensures that only vanishingly small concentrations of ethanol and methanol reach the peripheral circulation. With the use of highly sensitive and specific analytical methods, the concentrations of ethanol and methanol in body fluids obtained from healthy abstaining individuals ranges from 0.04 to 0.1 mg/dL.^{70,71}

Ethanol and methanol compete for binding sites on the Class I isozymes of ADH, which show a stronger preference for the oxidation of ethanol.⁵⁷ As a consequence, during metabolism of ethanol, the concentration of methanol in blood increases and remains on a more or less constant level, until blood ethanol decreases below 20 mg/dL (~4.3 mmol/L) (Figure 5.4.4). Thereafter, methanol is cleared with a half-life of 2 to 3 h, which means that methanol can be detected in body fluids long after the concentration of ethanol has returned to baseline or endogenous levels.^{37,72–74} This protracted wash-out of methanol opens the possibility of verifying recent drinking for several hours after ethanol has been cleared from the body.

Analysis of blood and urine methanol is included in some forensic investigations, when accountability for road traffic and workplace accidents are investigated.³⁸ Besides the acute effects of

Figure 5.4.4 Elimination kinetics of ethanol and methanol in two alcoholics during detoxification. Note that the concentration of methanol in blood remains fairly constant at about 1 mg/dL until the ethanol concentration decreases toward zero.

alcohol on performance and behavior, many people are impaired the morning after an evening's heavy drinking; these post-intoxication effects of heavy drinking are known as hangover (see Chapter 5.1).

The higher affinity of ADH for oxidation of ethanol compared with methanol also explains the mechanism behind the therapeutic usefulness of ethanol in treating methanol poisoning. Ethanol is given by intravenous infusion to reach and maintain a blood ethanol concentration of about 100 to 120 mg/dL, which effectively blocks the metabolism of methanol into its toxic metabolites formaldehyde and formic acid.⁷⁵ In the meantime, the more dangerous methanol is removed from the blood by dialysis and bicarbonate can be administered to counteract metabolic acidosis.⁷⁶ However, there are some reservations against the continued use of this antidote, because ethanol exerts a pronounced effect on the central nervous system and should not be used in treating children who inadvertently ingest methanol (wood alcohol).⁷⁷ The antidote currently in vogue for treating people poisoned with methanol is 4-methyl pyrazole (fomepizole), a competitive inhibitor of ADH.^{78,79}

Although alcoholic beverages are primarily mixtures of ethanol and water, they also contain a multitude of other chemical compounds, albeit at extremely low concentrations. These other substances, which are produced as by-products of the fermentation process, are collectively known as congeners and impart the smell and flavor to the alcoholic beverage.⁸⁰ Methanol is a ubiquitous congener and is present in beer (0.1 to 1 mg/dL), red and white wines (2 to 10 mg/dL), gin and whisky (0.1 to 20 mg/dL), and brandies and cognac (20 to 200 mg/dL).⁸¹ Accordingly, a raised concentration of methanol in blood and other body fluids after drinking alcoholic beverages could partly be explained by its presence as a congener, and also because of the metabolic interaction with ethanol via competitive inhibition of ADH.⁸² Finding a blood methanol concentration above 1 mg/dL suggests accumulation during a period of long-term heavy drinking (days or weeks), and some feel this furnishes a test for chronic alcohol abuse (see also Section 5.4.4.7).^{83–85} However, care is needed to ensure that the alcoholic beverage consumed does not contain abnormally high concentrations of methanol.^{81,86,87}

5.4.3.4 Conjugates of Ethanol Metabolism

The glucuronidation pathway of drug metabolism, including the conjugation of hydroxyl groups in aliphatic alcohols, was discovered more than a century ago.⁸⁸ Shortly after, it was found that ethanol was converted into ethyl glucuronide (EtG) and this minor metabolite was identified in urine.⁸⁹ However, interest in this non-oxidative pathway of ethanol metabolism was hampered, owing to the complexity of the analytical methods needed to determine reliably EtG concentrations in body fluids.^{90,91} The advent of modern analytical techniques, such as the highly sensitive and

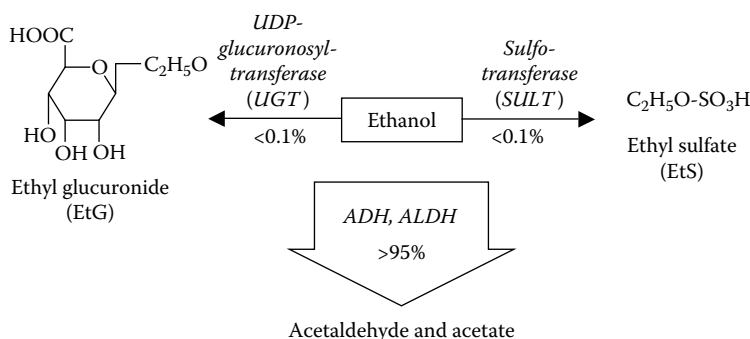

Figure 5.4.5 Schematic diagram illustrating the relative importance of the oxidation (phase I) and non-oxidative conjugation (phase II) elimination pathways for ethanol in the human body.

specific gas and liquid chromatography combined with mass spectrometry (GC-MS and LC-MS),⁹² radically changed the situation and spawned in a new area of biomedical alcohol research. Careful studies showed that only a very small fraction of the ingested ethanol (<0.1%) undergoes phase II conjugation reactions with glucuronic acid or sulfuric acid to produce EtG and ethyl sulfate (EtS), respectively (Figure 5.4.5).^{93,94} These soluble non-oxidative metabolites of ethanol are excreted with the urine, for several hours longer than ethanol itself.^{93,95–97}

After acute alcohol ingestion, there is no accumulation of EtG in body fluids,⁹⁸ although it may be retained in hair.⁹⁹ The advantage of hair over other body media for drug analysis is the extended window of detection offered, and, based on segmental analysis and an average growth rate, some idea can be obtained as to when the drug was last being used.¹⁰⁰ Determination of EtG in urine provides a means to verify whether a person has recently been drinking alcohol, for much longer than ethanol is detectable in body fluids. The resulting higher sensitivity of the EtG test, compared with analysis of ethanol itself, has obvious practical advantages as an acute marker of alcohol consumption.

The availability of improved analytical methods for EtG based on mass spectrometry (GC-MS and LC-MS)^{95,101,102} has allowed several research groups to make detailed studies of this trace metabolite of ethanol as a sensitive and specific biomarker of acute alcohol consumption.^{21,103} However, as expected from knowledge of glucuronides in general, EtG is sensitive to urine dilution. The EtG concentration in urine can be lowered markedly by drinking large amounts of fluid prior to voiding, whereas this does not influence the EtG/creatinine ratio.⁹³ Furthermore, EtG is sensitive to enzymatic hydrolysis, so if biological samples are contaminated with certain bacteria containing β -glucuronidase (e.g., *Escherichia coli* which is common in urinary tract infections), this represents another reason for obtaining falsely low or false-negative results.¹⁰⁴

Another phase II metabolic pathway, namely, sulfate conjugation, produces EtS and this minor metabolite of ethanol (<0.1%) is also excreted in urine.^{94,97} EtS shows similar excretion kinetics to EtG,^{94,97,105,106} but, in contrast to EtG, it is apparently not sensitive to bacterial hydrolysis.¹⁰⁴ Other minor metabolites of ethanol with potential use as alcohol biomarkers include ethyl nitrite and ethyl phosphate.¹⁰⁷

5.4.3.5 Fatty-Acid Ethyl Esters

Fatty acid ethyl esters (FAEE), such as ethyl palmitate and ethyl oleate, are esterification products of fatty acids and ethanol synthesized through the action of the enzyme FAEE synthase. The presence of these short-chain esters in samples of blood, tissue, or hair has been proposed as a biomarker of alcohol intake with clinical and forensic applications.^{100,108–110} After alcohol intake, the serum concentration of FAEE initially closely parallels that of ethanol (e.g., similar time for

peak concentrations) but, because of a very slow terminal elimination phase, FAEE persists in the blood for some time after ethanol is no longer detectable.^{111,112} The elimination rate of FAEE is faster than for some other acute alcohol biomarkers, implying a lower sensitivity for recent drinking.^{112,113} Increasing evidence indicates that FAEE may be toxic metabolites and, as such, possible mediators of ethanol-induced organ damage.¹¹⁴

5.4.3.6 Metabolites of Serotonin

Studies have shown that the metabolic interaction between ethanol and serotonin (5-hydroxytryptamine) can help to detect recent alcohol consumption. 5-Hydroxytryptophol (5HTOL) is normally a minor metabolite of serotonin, but the proportion of this metabolite increases dramatically in a dose-dependent manner after drinking alcohol. At the same time, 5-hydroxyindole-3-acetic acid (5HIAA), the major metabolite under normal conditions, is concomitantly decreased.^{115,116} Experiments with liver homogenates suggest that the shift in serotonin metabolism occurs because of competitive inhibition of ALDH by the acetaldehyde derived from oxidation of ethanol.¹¹⁷ Furthermore, during the metabolism of ethanol and acetaldehyde, the reduced coenzyme NADH is present in excess and the redox state of the liver shifts to a more reduced potential, both in the cytosol and mitochondria compartments. This alters the equilibrium between several other endogenous NAD-dependent reactions, such as lactate:pyruvate and β -hydroxybutyrate:acetoacetate. The combined influences of a competitive inhibition of ALDH and altered redox state of the liver promote formation of 5HTOL at the expense of 5HIAA.^{118,119} Most importantly, however, the urinary excretion of 5HTOL will not normalize until several hours after blood and urinary ethanol reaches zero (Figure 5.4.6).¹¹⁶ On the basis of this time lag, an increased urinary concentration of 5HTOL was suggested and used as a sensitive biochemical marker of recent drinking.^{120–122}

Expressing 5HTOL as a ratio 5HTOL/5HIAA, rather than 5HTOL/creatinine, improves test accuracy because dietary serotonin (high amounts in banana, pineapple, kiwi fruit, and walnuts) might otherwise cause false-positive results, owing to a general increase in the urinary output of both serotonin metabolites.¹²³ This device also compensates for variations in the concentration of 5HTOL caused by urine dilution after drinking fluids. To discriminate between a normal and elevated urinary ratios of 5HTOL/5HIAA, a cutoff limit of 15 nmol/ μ mol (i.e., 1.5%) is recommended for use in clinical practice.¹²² This threshold value is based on studies with alcohol-free subjects of both Caucasian and Asian origin.¹²⁴ The 5HTOL/5HIAA ratio remains stable both within-days and between-days during periods of abstinence, and the metabolites are also relatively uninfluenced during transport, handling, and long-term storage of the urine specimens. Neither

Figure 5.4.6 Time course of concentrations of ethanol and the ratio of 5-hydroxytryptophol (5HTOL) to 5-hydroxyindole-3-acetic acid (5HIAA) in urine after a healthy volunteer drank a single moderate dose of ethanol. The longer recovery time for the 5HTOL/5HIAA ratio is clearly evident.

gender nor genetic variations in ADH and ALDH isozyme patterns seem to influence the baseline ratio of 5HTOL/5HIAA.^{37,124}

An increased urinary 5HTOL/5HIAA furnishes a specific and more sensitive laboratory test of recent drinking than measuring the concentration of ethanol or methanol in body fluids.^{37,74} The major advantage of 5HTOL/5HIAA over ethanol and methanol is that a raised serotonin metabolite ratio persists for several hours longer, thereby improving the ability to detect covert drinking. Furthermore, in contrast to methanol, the baseline ratio of 5HTOL/5HIAA is not elevated after prolonged intermittent alcohol intake and can therefore identify recent drinking in moderate as well as chronic drinkers.⁹⁸ Apart from alcohol ingestion, the only factor known to increase the 5HTOL/5HIAA ratio is treatment with the ALDH inhibitors disulfiram (Antabuse) and cyanamide.¹²⁵ Another drawback is that urinary 5HTOL testing at present requires rather sophisticated analytical techniques based on GC-MS or LC-MS.^{122,126,127}

Testing of urinary 5HTOL has, for example, been used in clinical practice, to detect alcohol use and single lapses during treatment of alcohol-dependent subjects in an outpatient setting,^{128,129} in heroin addicts on methadone maintenance,³⁹ and in surgical patients with chronic alcohol abuse.¹³⁰ Furthermore, testing for 5HTOL/5HIAA has applications in forensic medicine, to distinguish ingested from microbially formed ethanol, which might occur in post-mortem specimens or in urine from individuals with diabetes or others with urinary tract infections.^{29,30,32,131} The 5HTOL/5HIAA ratio has also been recommended for use during official forensic investigations of aviation crashes,¹³² where the risk for post-mortem synthesis of ethanol is exaggerated.^{126,133}

5.4.4 Tests of Chronic Alcohol Ingestion

5.4.4.1 *Gamma-Glutamyl Transferase*

For many years, the activity of the enzyme gamma-glutamyl transferase (GGT) in serum has been the most widely used biochemical test for alcohol abuse.¹³⁴ GGT is a membrane-bound glycoprotein widely distributed in various organs, and plays an important role in glutathione synthesis, amino acid transport, and peptide nitrogen storage. Only trace amounts are normally present in serum from healthy subjects. However, in liver damage, for example, resulting from continuous heavy drinking, a significant elevation in serum GGT occurs.^{135,136} Although the mechanisms responsible are not known exactly, damage to hepatocytes and/or induction of hepatic GGT may cause the enzyme to leak into the blood.^{137,138} After withdrawal from ethanol, GGT returns to normal levels within approximately 4 to 5 weeks.

The determination of GGT is routinely included in blood-chemistry profiles on admission to hospital. The major disadvantage of GGT is that the serum level is raised by a variety of other conditions besides alcohol misuse, thereby reducing its diagnostic specificity.^{134,139,140} For example, several common medications, such as barbiturates and antiepileptics, and various liver disorders of non-alcohol origin, also elevate serum GGT. Moreover, accepted normal ranges depend on nutritional status, body weight, age, and gender of the individual. Different threshold limits depicting abnormal values need to be applied for women and men separately. Although GGT has limited utility as a single screening test for hazardous alcohol consumption in nonselected populations,¹⁴¹ many of the confounding factors are well known and can often be excluded or controlled for in clinical situations. The major advantage of GGT as a marker of alcohol abuse is its ready availability at low cost from most clinical laboratories.

5.4.4.2 *Aspartate and Alanine Aminotransferase*

Other standard tests of liver dysfunction caused by hazardous drinking include raised serum levels of the transaminases aspartate (AST) and alanine aminotransferase (ALT), which are enzymes involved in amino acid metabolism. Like GGT, certain medical conditions other than alcohol abuse

can cause abnormal AST and ALT values, and both these markers are typically less sensitive, though somewhat more specific, than GGT.^{142,143} The ALT-to-AST ratio,¹³⁹ as well as the proportion of mitochondrial to total AST,^{144,145} has been suggested as a way to discriminate alcohol-induced from non-alcoholic liver disease, but this has not been confirmed in studies in unselected populations.^{146,147} The transaminases may be useful in combination with other biochemical tests,¹⁴⁸ and for follow-up of patients with already established alcoholic liver disease.¹⁴⁹

5.4.4.3 Erythrocyte Mean Corpuscular Volume

Mean corpuscular volume (MCV) is included as part of a routine blood count and indicates the size of the red blood cells (erythrocytes). An elevated MCV is often observed in alcoholic patients,¹⁵⁰ and this parameter has been widely used as a marker of excessive alcohol consumption.¹⁵¹ The underlying cause of swelling of the red cells is unknown, but may be a direct toxic effect of ethanol or the alcohol-mediated deficiency of folic acid. The sensitivity of MCV as a biochemical marker of heavy drinking is much too low to motivate its use as a sole indicator of this condition.¹⁵² There are other explanations for elevated MCV besides continuous heavy drinking, such as smoking, which is very common in alcoholics.^{153,154} However, MCV shows a higher specificity than GGT,^{148,151,155,156} and it is often used in combination with other biochemical parameters and offers the added advantage that it takes longer (several months) for MCV to recover to normal values after cessation of heavy drinking.

5.4.4.4 Carbohydrate-Deficient Transferrin

The presence of an abnormal glycoform pattern of the iron transport glycoprotein transferrin in serum, named carbohydrate-deficient transferrin (CDT), has emerged as the most reliable routine method for detection of continuous high alcohol consumption for 2 or more weeks.¹⁵⁷ The discovery of CDT as a marker of heavy drinking dates back more than 20 years.¹⁵⁸ The finding of an abnormal transferrin pattern in blood serum appears to be fairly specific for overconsumption of alcohol and recovers to normal during periods of abstinence with a half-life of ~1.5 to 2 weeks.^{158,159}

Normal variations in transferrin glycoform patterns could stem from genetic polymorphism, the degree of iron saturation, or the number of terminal sialic acid residues in the two *N*-linked oligosaccharide chains (*N*-glycans).^{160–162} The most abundant glycoform in serum is tetrasialotransferrin, containing two biantennary carbohydrate chains making a total of four terminal sialic acid residues. Studies have shown that after prolonged heavy drinking, the abundance of transferrin molecules lacking one or both of the entire *N*-glycans (disialo- and asialotransferrin, respectively) increases appreciably (Figure 5.4.7).^{163–165} The underlying mechanism that causes elevation of CDT may involve acetaldehyde-mediated inhibition of the enzymes responsible for glycosyl transfer.^{166–168}

CDT is a much more specific indicator of excessive drinking than any of the other currently used laboratory tests, and it is also assumed to have better sensitivity for early detection of alcohol abuse compared to GGT.^{158,169,170} However, it should be noted that a person typically needs to drink ~50 to 80 g ethanol or more daily over a period of at least 1 to 2 weeks before abnormal CDT values develop.^{158,171,172} Falsely high or low CDT results are obtained in cases of uncommon genetic transferrin variants,^{162,173–175} and in rare congenital disorders of glycosylation (CDG).^{176,177} It is generally agreed that the CDT content should be expressed in relation to total transferrin (i.e., %CDT), instead of as an absolute amount (e.g., mg/L). This device has an analytical advantage, because an abnormally high or low serum transferrin concentration may otherwise render falsely high or low CDT results.^{178–180}

Because the disialo- and asialotransferrin glycoforms lacking 2 or 4 terminal sialic acid residues are less negatively charged, and thereby have higher isoelectric points, than tetrasialotransferrin (pI

Figure 5.4.7 Schematic illustration of the changes in transferrin glycosylation pattern caused by heavy alcohol consumption. Tetrasialotransferrin is normally the major glycoform (~75 to 80%), but prolonged heavy drinking results in increased levels of transferrin molecules lacking one or both of the entire *N*-glycans (disialo- and asialotransferrin, respectively).

~ 5.4), they are readily separated by techniques such as isoelectric focusing (IEF), capillary electrophoresis (CE), and ion-exchange chromatography (e.g., HPLC).^{159,161,181–183} Although all these methods are laborious and rather time-consuming for routine use, especially when a large number of samples must be analyzed daily, an advantage is the visible documentation and, therefore, the reduced risk of obtaining false-positive results owing to genetic variations or other chromatographic interferences.¹⁶² The first direct immunoassay for determination of %CDT was recently introduced, which at the same time appears to be insensitive to genetic transferrin variants.^{184,185}

5.4.4.5 Phosphatidylethanol

Another non-oxidative pathway of ethanol elimination is the reaction with membrane phospholipids to produce phosphatidylethanol (PEth). PEths are unique phospholipids formed in cell membranes only in the presence of ethanol,^{186,187} and have been proposed as a highly specific marker of chronic heavy drinking within the previous week(s). After alcoholic patients, with a self-reported daily intake of 60 to 300 g ethanol for at least 1 week, were admitted to a detoxification program, PEth was detectable in their blood for another 2 weeks.^{188,189} Moreover, the sensitivity of PEth was reported to be greater than, or at least equal to, that of CDT.¹⁹⁰ Improved analytical procedures for quantitation of PEth will allow for routine clinical use of this biomarker.¹⁹¹ However, a recently recognized problem, interfering with the specificity of PEth as a biomarker of prolonged heavy drinking, is the risk of artifact formation of PEth during storage if the blood sample contains ethanol.¹⁹²

5.4.4.6 Acetaldehyde Adducts

Acetaldehyde, the proximate metabolite of ethanol oxidation, is a highly reactive chemical species and forms adducts with various biomolecules, including DNA, phospholipids, and proteins.^{193–195} The binding of acetaldehyde to hepatocellular macromolecules has been suggested as the underlying cause of alcoholic liver injury.^{196–198} Measurement of “whole blood-associated” acetaldehyde, acetaldehyde-hemoglobin adducts, or antibodies that recognize acetaldehyde-modified structures, have emerged as possible biochemical markers of excessive drinking.^{199–202} However, some of these positive results were obtained *in vitro* after nonphysiological concentrations of acetaldehyde were administered, and the relevance of these findings *in vivo* has been a matter of debate. Although analysis of various forms of bound acetaldehyde have shown promising results, and, indeed, were found to be more sensitive for the detection of chronic excessive drinking than GGT and MCV,^{203,204} more work is needed to determine the reliability and diagnostic potential for

identification of heavy drinking in unselected populations. Moreover, most of the currently used methods for quantification of acetaldehyde adducts are probably too complex for routine purposes.

5.4.4.7 Other Potential Tests or Markers of Chronic Drinking

Numerous other candidate biochemical tests of alcohol use and abuse have been evaluated over the years, but only a few have gained general acceptance.^{18,19} The major deficiencies are either poor sensitivity or specificity for alcohol abuse, or requiring laborious and time-consuming assay procedures. Some markers have not been tested in sufficiently large enough cohorts of subjects with use of appropriate control groups.

Several studies have reported that alcoholics after a recent or ongoing chronic drinking binge develop a lower blood, or erythrocyte, ALDH activity compared to healthy controls.²⁰⁵ However, there is a considerable inter-individual overlap between heavy and moderate consumers of alcohol in this respect, and even between heavy drinkers and teetotalers.^{206,207} Consequently, to obtain sufficient sensitivity, the specificity of this enzyme marker must be very low (see Section 5.4.2). In addition, several drugs, including the alcohol-sensitizing agents disulfiram (Antabuse) and cyanamide, as well as environmental factors like smoking, may cause long-lasting depression of the ALDH activity in blood.²⁰⁵

An increased level of the lysosomal enzyme β -hexosaminidase has been observed in serum from alcoholics, and was proposed as a more sensitive marker of heavy drinking than GGT.^{208,209} In a study on patients undergoing detoxification, the B-isoforms of the enzyme compared well with CDT in terms of sensitivity and disappearance rate from the circulation during the alcohol withdrawal phase.²¹⁰ However, the sensitivity is much lower when unselected populations are examined,²¹¹ and it should be noted that serum β -hexosaminidase is elevated not only after alcohol abuse but also in non-alcoholic liver disease, diabetes, hypertension, and pregnancy,²¹² implying a low specificity for alcohol.

As mentioned earlier in this chapter (Section 5.4.3.3), trace amounts (~ 0.1 mg/dL) of both methanol and ethanol are produced naturally in the body during the course of intermediary metabolism or via bacteria in the colon acting on dietary carbohydrates. When the blood-ethanol concentration exceeds 20 mg/dL, the hepatic Class I isozymes of ADH are saturated and therefore fully engaged in the clearance of ethanol from the body. Methanol, however, continues to be produced from endogenous substrates and its oxidation is hindered, because of a competition with ethanol for available ADH enzymes. Furthermore, the concentration of methanol in blood increases during the drinking spree, owing to the congener content of the alcoholic beverages consumed. Recent studies have shown that this metabolic interaction between methanol and ethanol can help to distinguish between acute and chronic drinking practices.²¹³ After acute intake of ethanol, the BAC rarely exceeds 150 mg/dL and the corresponding blood methanol is generally below 0.5 mg/dL. However, if the BAC reaches 250 mg/dL, this suggests a period of continuous heavy drinking and the concentration of methanol now tends to increase in body fluids.²¹⁴ Depending on the intensity and duration of the drinking spree, as well as the methanol content of the drinks consumed,⁸¹ the concentration of methanol in blood might increase appreciably and sometimes exceeds 1 mg/dL. Indeed, this concentration threshold (>1 mg/dL) is assumed to indicate continuous heavy drinking and therefore has been used as a marker of chronic alcoholism.²¹³ Because the metabolism of methanol is blocked after BAC exceeds 20 mg/dL (see Figure 5.4.3), the longer lasting the drinking spree so that BAC never drops below 20 mg/dL, the higher will be the steady-state concentration of methanol. The analysis of methanol as well as other biochemical markers of alcohol abuse has been used in Germany, to decide on re-granting of driving licenses and whether a convicted drunk driver should receive treatment or punishment for this traffic crime.²¹³

5.4.5 Routine Clinical Use of Biochemical Tests for Excessive Drinking

5.4.5.1 Single Tests or Test Combinations?

As already indicated, most of the currently available standard laboratory tests lack sufficient sensitivity and/or specificity to warrant their use as sole evidence of heavy drinking. To increase diagnostic sensitivity, various combinations of markers have therefore been evaluated, such as two or more of GGT, MCV, AST, ALT, and CDT, as well as many others.^{215–217} Even though combinations of markers tend to increase diagnostic sensitivity, at the same time this approach might reduce diagnostic specificity.^{218–220} Furthermore, using multiple markers tends to complicate the interpretation of results and also increases the overall costs.

Nevertheless, a useful approach is to combine markers each independently associated with heavy drinking.²⁶ Whereas a strong association is usually obtained between liver function tests like GGT, AST, and ALT, this is not the case for GGT and CDT.^{221–223} Rather, in one study, several of the highest CDT levels were observed in alcoholic subjects possessing normal or only moderately elevated GGT values, and vice versa.²²² This was further confirmed by another study in which a negative correlation between CDT and the severity of liver disease was reported.²²⁴ It seems that the combined use of GGT and CDT significantly improves identification of heavy drinkers and those at risk of becoming dependent on alcohol.^{219,222,223}

A combination of short-term and long-term markers of alcohol consumption has also been used successfully during outpatient treatment of alcohol-dependent subjects.^{128,129} Finding an increased CDT suggests the person has returned to continuous heavy drinking after a period of abstinence, whereas normal CDT but instead a positive morning breath alcohol test or, preferably, other more sensitive biomarkers of acute alcohol intake, such as urinary 5HTOL, EtG or EtS, will identify single lapses.

5.4.5.2 Screening for Excessive Drinking in Unselected Populations

Many biochemical screening markers used for the early detection of harmful consumption of alcohol give excellent results (i.e., high sensitivity and specificity), when studies are carried out on selected populations, e.g., alcoholics undergoing detoxification as compared to moderate drinkers or teetotalers. By contrast, in studies on single individuals, and when screening people from the general population, most tests are less satisfactory, mainly because of a considerable overlap between the values obtained for heavy and moderate drinkers. Furthermore, because certain medical and environmental conditions may influence the test results, false positives are not uncommon. An example illustrates this point. Assuming that the prevalence of excessive drinking is 10%, a marker with 90% sensitivity and specificity will correctly identify 9 of 10 heavy drinkers in a study population of 100, but, at the same time, incorrectly identify 9 of 90 healthy subjects as having drinking problems. Thus, the chance of a correct classification under these conditions is only 50% (the positive predictive value). For most of the currently available laboratory markers of alcohol abuse, a single abnormal test result may thus be difficult to interpret in an unequivocal way, unless confirmed in a repeated test or by complementary testing to exclude other potential causes.

Another important issue is the time delay between drinking and sampling. Because different alcohol biomarkers have different life spans, the time since the last drink should always be considered, when evaluating the sensitivity of a test. The most widely used markers GGT and CDT, for example, have biological half-lives of ~2 to 3 weeks, so the specimen should preferably be collected no later than 1 week after admission to hospital or during alcohol withdrawal; otherwise the sensitivity of the test will be reduced considerably.

5.4.5.3 Treatment Follow-Up of Alcohol-Dependent Patients

Monitoring changes over time in a number of biomarkers of excessive drinking, such as CDT and GGT, during a 2- to 4-week period of alcohol withdrawal (e.g., during hospitalization or other inpatient treatment, or treatment with disulfiram), allows the most sensitive single marker to be identified.^{222,225} If values normalize on withdrawal, this confirms that alcohol was most likely the cause of the abnormal test results. After discharge from the hospital, monitoring excessive drinking should continue on a routine basis in connection with return visits to the clinic. This facilitates early identification of relapse,²²⁶ when combined with an early morning breath alcohol test or a more sensitive biomarker of acute drinking such as 5HTOL, EtG, and EtS.²⁶ The optimal testing frequency depends in part on the life span of the marker in question.²²⁷ Giving feedback to patients about the results of the tests, for example, by presenting these graphically, can be very informative and may also improve self-report and treatment outcome.^{228,229} However, if this strategy is used, it is imperative that the results are reliable (i.e., using highly specific tests); otherwise patients may become demoralized and lose faith in the use of laboratory markers.

The use of repeated testing also makes it possible to use individualized instead of population-based reference limits for each biomarker, thereby improving considerably the reliability of results.^{129,149} The recommended cutoff limits between normal and abnormal are usually based on a Gaussian distribution in healthy controls. However, because of inter-individual variations, some subjects with very low baseline values probably need to drink much larger amounts of alcohol than those with considerably higher baseline values, in order to exceed the critical threshold limit. Therefore, by introducing individualized cutoffs, detection of relapse drinking can be significantly improved.^{129,230}

5.4.6 Trait Markers of Alcohol Dependence

Eugenic studies conducted during the late 1800s demonstrated that excessive drinking, drunkenness, and alcohol dependence run in families. Unequivocal evidence for a genetic component in alcoholism and addiction came from the widely publicized adoption and twin studies.^{231,232} Later research dealing with the inheritance of alcohol dependence led to the definitions of *type 1* and *type 2* subtypes, which have become widely accepted.²³³ It seems that some people are more predisposed to becoming dependent on alcohol when they start to drink regularly, and, for this reason, efforts have been made to develop trait markers of alcohol dependence.^{234–236}

Examples of such genetic or trait markers of a vulnerability to develop alcohol dependence include various neurotransmitter systems, such as the dopamine D₂ receptor gene, the activity of monoamine oxidase (MAO), and adenylyl cyclase (AC) enzymes and the serotonin transporter (5HTT), as well as the neuropeptides (e.g., neuropeptide Y, NPY), which are all involved in various aspects of compulsive, impulsive, and addictive behavior, including pleasure seeking and reward areas of the brain.^{236,237} A significantly lower activity of MAO in blood platelets of alcoholics compared to controls was reported,²³⁸ although concerns have been raised about the exact mechanism causing this difference.²³⁹ Tobacco use, for example, which is common in alcoholics, can also lower MAO activity.²⁴⁰

Hitherto, the only clear-cut evidence linking alcohol use and abuse to genetics is the polymorphisms observed for ADH and ALDH enzymes in Japanese and some other Asian populations.²⁴¹ The presence of an inactive mitochondrial ALDH2 isozyme makes these individuals hypersensitive to acetaldehyde, which reaches an abnormally high concentration in blood even after drinking small amounts of alcohol. This inborn Antabuse-like reaction creates an aversion to alcohol, which influences drinking behavior and decreases the risk of becoming dependent on alcohol and developing alcoholic liver disease.²⁴²

5.4.7 Conclusions

Alcohol abuse and dependence are major risk factors for serious ill-health, social, and economic problems, and excessive drinking is a common cause of injuries and premature death.²⁴³ Early identification of those who overindulge in drinking enhances the possibility of finding a successful treatment. However, obtaining accurate information about a person's drinking habits represents one of the major problems in the detection of excessive alcohol consumption. Self-reports of drinking practices during interview or in diagnostic questionnaires are widely used by clinicians for this purpose. Experience has shown that people with alcohol-related problems may deliberately deny or underreport the actual amounts they consume, at least in the early stages of misuse. For this reason, erroneous classification and underdiagnosis of alcohol abuse is fairly common.^{146,244,245} To rectify this problem, efforts have been made to discover biochemical and hematological abnormalities associated with excessive drinking. These markers need to be sufficiently sensitive and specific to identify heavy drinkers, even when the person refrains from drinking prior to visiting a physician.

The perfect biochemical test should be specific for alcohol and also exhibit high sensitivity to hazardous drinking habits. Furthermore, the test should be inexpensive and yield rapid results with easily available specimens such as urine, saliva, or blood. Measuring ethanol in body fluids or breath is of course the most highly specific alcohol test, but, because ethanol is eliminated fairly rapidly from the body, the sensitivity of this test is low. Most of the currently available laboratory markers perform well, when selected high-risk populations are being compared, but they are less satisfactory in randomly selected individuals. An alcohol breath test is simple to perform but this needs to be combined with a battery of more sensitive biochemical indicators, as discussed in this chapter, such as GGT and CDT. When the aim is to test for acute alcohol intake or relapse, the recommended markers besides ethanol are 5HTOL, EtG, or EtS.

Alcohol is a legal, socially accepted, recreational drug, although the patterns of alcohol consumption, in terms of quantity and the choice of beverage, differ widely between individuals and nations. Furthermore, a pattern of drinking that might be harmless to one individual might damage health in another, owing to various genetic influences and risk of becoming dependent on alcohol (see Chapter 5.1). Over the past 10 to 15 years, considerable interest has developed in using biochemical markers to document alcohol use and abuse in a more objective way, compared with clinical interviews and screening questionnaires about the negative consequences and experiences after a drinking spree. Identifying people at greatest risk for developing alcohol problems is a challenge, and positive findings will ensure adequate and early treatment and rehabilitation programs. In this connection, biochemical markers have emerged as essential tools to verify abstinence and to detect relapse drinking in patients undergoing treatment for alcoholism.

6.1 THE DOPAMINE TRANSPORTER AND ADDICTION

William M. Meil, Ph.D.¹ and John W. Boja, Ph.D.²

¹ Department of Psychology, Indiana University of Pennsylvania, Indiana, Pennsylvania

² U.S. Consumer Product Safety Commission, Directorate for Health Sciences, Bethesda, Maryland

Dopamine transporter (DAT) is a distinctive feature of dopaminergic neurons, discovered more than 20 years ago.¹⁻⁵ DAT is the major mechanism for the removal of released dopamine (DA). DA is actively transported back into dopaminergic neurons via a sodium- and energy-dependent mechanism.⁶⁻⁸ Like other uptake carriers, DAT is regulated by a number of drugs including cocaine, amphetamine, some opiates, and ethanol. It is this interaction with DAT and the resulting increase in synaptic DA levels that have been suggested to be the basis for the action of several drugs of abuse. The dopaminergic hypothesis of drug abuse has been proposed by a number of researchers.^{9,10} Di Chiara and Imperato¹¹ observed the effects of several drugs of abuse on DA levels in the nucleus accumbens and caudate nucleus using microdialysis. Drugs such as cocaine, amphetamine, ethanol, nicotine, and morphine were all observed to produce an increase in DA, especially in the nucleus accumbens. Drugs that are generally not abused by humans, such as bremazocine, imipramine, diphenhydramine, or haloperidol, decreased DA or increased DA in the caudate nucleus only. It was, therefore, concluded¹¹ that drugs abused by humans

preferentially increase brain DA levels in the nucleus accumbens, whereas psychoactive drugs not abused by humans do not. By employing this hypothesis of drug reward as a starting point, this chapter reviews evidence regarding the function of DAT and the interaction of several drugs of abuse on DAT.

6.1.1 Dopamine Uptake

The uptake of DA depends on a number of factors^{4-6,12-15} including temperature, sodium,¹⁶⁻¹⁹ potassium,^{6,16} chloride^{7,20} but not calcium.⁶ Krueger²¹ suggested that dopamine transport occurred by means of two sodium ions and one chloride ion carrying a net positive charge into the neuron, which is utilized to drive DA against its electrochemical gradient. More recently, McElvain and Schenk²² proposed a multisubstrate model of DA transport. In this model it was proposed that either one molecule of DA or two sodium ions bind to DAT in a partially random mechanism. Chloride binds next and it is only then that the DAT translocates from the outside of the neuron to the inside (Figure 6.1.1). Cocaine inhibition of DA transport occurs with cocaine binding to the sodium-binding site and changing the conformation of the chloride-binding site, thus preventing the binding of either and ultimately inhibiting dopamine uptake. DA uptake by cocaine appeared to be uncompetitive inhibition whereas the binding of sodium and chloride are competitively inhibited. This action is present only with neuronal membrane-bound DAT because cocaine does not appear to inhibit the reuptake of DA to the vesicles via the vesicular transporter.²³ Moreover, site-directed mutations of DAT hydrophobic regions²⁴ or the carboxyl-terminal tail²⁵ have resulted in differential effects on cocaine analogue binding and dopamine uptake.

Figure 6.1.1 The dopamine transporter terminates the action of released dopamine by transport back into the presynaptic neuron. Dopamine transport occurs with the binding of one molecule of dopamine, one chloride ion, and two sodium ions to the transporter; the transporter then translocates from the outside of the neuronal membrane into the inside of the neuron.²² Cocaine appears to bind to the sodium ion binding site. This changes the conformation of the chloride ion binding site; thus dopamine transport does not occur. This blockade of dopamine transport potentiates dopaminergic neurotransmission and may be the basis for the rewarding effects of cocaine.

A recent review of the literature on the amino acid structure of DAT stated that uptake of dopamine is dependent on multiple functional groups of amino acids within DAT.²⁶ The authors suggested that the amino acid functional groups of Phe⁶⁹, Phe¹⁰⁵, Phe¹¹⁴, Phe¹⁵⁵, Thr²⁸⁵, Phe³¹⁹, Phe³¹¹, Pro³⁹⁴, Phe⁴¹⁰, Ser⁵²⁷, Phe⁵²⁰, Tyr⁵³³, and Ser⁵³⁸ in rat DAT and Val⁵⁵ and Ser⁵²⁸ in human DAT appear to be involved in DAT uptake.

6.1.2 Abused Drugs and the Dopamine Transporter

6.1.2.1 Cocaine

Cocaine has several mechanisms of action: inhibition of DA, norepinephrine, and serotonin reuptake, as well as a local anesthetic effect. While the stimulating and reinforcing effects of cocaine have been recognized for quite some time, it was not until recently that the mechanism for these effects was elucidated. The stimulatory effects of cocaine were first associated with the ability of cocaine to inhibit the reuptake of DA.^{27,28} Saturable and specific binding sites for [³H] cocaine were then discovered by Reith using whole mouse brain homogenates.²⁹ When striatal tissue was utilized as the sole tissue source, Kennedy and Hanbauer³⁰ were able to correlate the pharmacology of [³H]cocaine binding and [³H]DA uptake inhibition and, thereby, hypothesized that the binding site for [³H]cocaine was in fact DAT. By using the data from binding experiments, it has been possible to correlate the strong reinforcing properties of cocaine with blockade of DAT rather than inhibition of either the serotonin (SERT) or norepinephrine transporters (NET).^{31,32}

By using radiolabeled cocaine^{33–35} or analogues of cocaine such as WIN 35,065-2,³⁰ WIN 35,428,^{33,34} RTI-55,^{35–43} and RTI-121,^{44,45} it is possible to visualize the distribution of these drugs within the brain; the pattern of binding demonstrated by cocaine and its analogues appears to coincide with the distribution of dopamine within the brain. Areas of the brain with the greatest amount of dopaminergic innervation, such as the caudate, putamen, and nucleus accumbens, also demonstrate the greatest amount of binding, whereas moderate amounts of binding are observed in the substantia nigra and ventral tegmental areas. Recently specific antibodies to the DAT have been developed.⁴⁶ Visualization of the distribution of DAT within the brain using these antibodies demonstrated that there was a good correlation with cocaine binding.

Several unrelated compounds have been demonstrated to bind to the DAT, such as [³H]mazindol,⁴⁷ [³H]nomifensine,⁴⁸ and [³H]GBR 12935.⁴⁹ However, while these compounds also inhibit the reuptake of DA, they do not share the powerful reinforcing properties of cocaine. The question of why these compounds are non-addictive while cocaine is quite addictive remains unanswered. Several possibilities exist: Schoemaker et al.⁵⁰ observed that [³H]cocaine binds to both a high- and low-affinity site on the DAT, whereas other ligands such as [³H]mazindol,⁴⁷ [³H]nomifensine,⁴⁸ and [³H]GBR 12935⁴⁹ bind solely to a single high-affinity site. This does not indicate that the two binding sites demonstrated by cocaine and its analogues^{43,44,51–54} represent two distinct sites, however, because both the high- and low-affinity sites arise from a single expressed cDNA for the DAT.⁵⁵ Another difference may be the pattern of binding, in that [³H]mazindol binds to different sites in the brain than those observed for [³H]cocaine.⁵⁴ In addition, the rate of entry into the brain is different for these different compounds. Mazindol and GBR 12935 have been demonstrated to enter the brain and occupy receptors much more slowly than cocaine.^{57,58} At the present time it is still unclear which of these or other possible factors promote the strong reinforcing properties of cocaine.

Recently, mice lacking the gene for DAT have been developed;⁵⁹ DA is present in the dopaminergic extracellular space of the homozygous mice almost 100 times longer than it is present in the normal mouse. The homozygous mice were hyperactive compared to normal mice and, as expected, cocaine did not produce any effect in the locomotor activity of the homozygous mice. These results provide further evidence to support the concept of the DAT as a cocaine receptor. However, mice lacking DAT do show cocaine reinforcement.^{60–63} Possible explanations for this observation include a role of SERT^{60,62} or NET in the psychoactive effects of cocaine.

6.1.2.2 Amphetamine

Amphetamine and its analogues, including but not limited to methamphetamine, methylenedioxymphetamine (MDA), and methylenedioxymethamphetamine (MDMA), increase brain DA levels.^{64–76} Amphetamine has been postulated to increase brain DA levels either by increasing DA release or by blocking DA reuptake. Hadfield⁷⁷ observed amphetamine blockade of DA reuptake; however, reuptake inhibition occurred only at doses of amphetamine ($ED_{50} = 65$ mg/kg) that were much higher than the doses observed to increase release. While reuptake blockade may play a role in the ability of amphetamine to elevate DA, blockade occurs only at doses near those that produce stereotypy or toxicity. On the other hand, amphetamine-stimulated DA release occurs at much lower doses. Amphetamine-stimulated DA release has been postulated to occur by two mechanisms: one involves the interaction of amphetamine with the DAT, which then produces a reversal of the DAT so that DA is transported out of neuron while amphetamine is transported out of the neuron.^{77–85} The other proposes passive diffusion of amphetamine-mediated alteration of vesicular pH.⁸⁴ Using human DAT-transfected EM4 cells, Kahlig⁸⁶ observed both a fast and slow efflux of dopamine following amphetamine stimulation suggesting that amphetamine releases DA via the DAT in a quantum-like manner resulting in a slow DA release and in a faster channel-like manner.

Besides this purported action on DAT, amphetamine has also been suggested to act upon the vesicular transporter as well. Pifl et al.⁸⁷ examined COS cells transfected with cDNA for either DAT or the vesicular transporter, or both. A marked increase in DA release was noted in cells that expressed both DAT and the vesicular transporter when compared to the release from cells that express only DAT or the vesicular transporter. The mechanism of action for amphetamine was further defined with the work of Giros et al.⁵⁹ In transgenic mice lacking the DAT, amphetamine did not produce hyperlocomotion or release DA.

In summary, the DAT appears to be the primary site of action for amphetamine-induced DA release via its activity on the DAT because amphetamine appears to employ DAT to transport DA out of the neuron while, at the same time, amphetamine may be sequestered in the neuron. The sequestered amphetamine then may release vesicular DA by altering vesicular pH or via interactions with the vesicular transporter.

6.1.2.3 Opiates

Opiate drugs share the ability to elevate extracellular DA concentrations in the nucleus accumbens,^{88–90} possibly implicating mesolimbic DA activity in the abuse liability of these compounds. Whereas the locomotor⁹¹ and reinforcing effects^{92,93} of opiates may occur through DA-independent pathways, there is also evidence for dopaminergic mediation of these effects.^{94,95} Lesions of dopaminergic neurons^{96,97} or neuroleptic blockade of DA receptors^{98,99} attenuate opiate reward as measured by intracranial electrical self-stimulation, conditioned place preference, and intravenous self-administration. In contrast to cocaine's ability to augment DA concentrations through direct action at DAT,¹⁰⁰ opiates appear to enhance DA concentrations primarily by indirectly stimulating DA neurons.^{101,102}

However, evidence suggests that some opiates also act at DAT. Das et al.¹⁰³ reported that U50-488H, a synthetic κ opiate agonist, and dynorphin A, an endogenous κ ligand, dose-dependently inhibit [³H]DA uptake in synaptosomal preparations from the rat striatum and nucleus accumbens. Inhibition of [³H]DA uptake by U50-488H was not reversed by pretreatment with the opiate antagonists naloxone and nor-binaltorphine, suggesting that this effect is mediated through direct action at DAT rather than an indirect effect at κ receptors. However, the effects of another κ opiate agonist, U69593, do not appear mediated by the DAT since U69593 failed to attenuate GBR 12909- and WIN 35,428-induced cocaine seeking behavior.¹⁰⁴

Meperidine, an atypical opiate receptor agonist with cocaine-like effects, has been shown to act at the DAT.¹⁰⁵ Meperidine inhibited [³H]DA uptake in rat caudate putamen with a maximal

effect less than that achieved with cocaine. This suggests that meperidine may predominantly act at the high-affinity transporter site. Meperidine also displaced [^3H]WIN 35,428 binding in a manner consistent with a single site affinity. Because meperidine shares key structural features with the phenyltropane analogues of cocaine, it is possible that these common structural features account for the cocaine-like actions of meperidine rather than any characteristics intrinsic to opiates. Similarly, fentanyl, a μ opiate agonist structurally related to meperidine, decreased [^{123}I] β -CIT binding in the basal ganglia of a single human subject and in rats, supporting the direct action of some opiates on dopamine reuptake.¹⁰⁶ In contrast, selective μ and opiate agonists failed to inhibit [^3H]DA uptake in the striatum and nucleus accumbens across the same range of doses. Morphine, a μ opiate agonist, also did not inhibit [^3H]DA uptake or displace [^3H]WIN 35,428 binding in the striatum¹⁰⁵ or displace [^3H]GBR 12935 binding in basal forebrain.¹⁰⁷ Conditioned place preference to morphine is increased in DAT knockout mice.¹⁰⁸

Although opiates and psychostimulants may possess different sites of action, it has been suggested that cross-sensitization of their addictive properties may result from overlapping neural targets. Examining the localization of κ -opioid receptor and DAT antisera in nucleus accumbens shell of the rat, κ -opioid receptor labeling was seen primarily in axon terminals and DAT labeling was observed exclusively in axon terminals. Thus, opiate agonists in the nucleus accumbens shell may modulate DA release primarily via control of presynaptic neurotransmitter secretion that may influence or be influenced by intracellular DA.¹⁰⁹

Although morphine appears to lack direct action at DAT, research suggests that chronic morphine may alter DAT expression. Repeated, but not acute administration of morphine to rats decreased the B_{max} of [^3H]GBR12935 binding in the anterior basal forebrain, including the nucleus accumbens, but not the striatum.¹⁰⁷ However, radioligand affinity was not different in either brain region. Neither acute nor chronic morphine administration inhibited binding at the serotonin transporter in the striatum or anterior basal forebrain, suggesting that transporter down-regulation was selective for brain regions important for the reinforcing and/or motivational properties of opiates. Because daily cocaine administration in rats also attenuates DA uptake in the nucleus accumbens, and not the striatum,¹¹⁰ chronic elevation of DA release and a subsequent reduction in DAT expression within the nucleus accumbens may prove important in the development of drug addiction. The effects of chronic morphine administration on DAT activity may also be related to withdrawal status of the animal. Rats implanted with morphine pellets for 7 days and examined with the pellets intact showed [^3H]GBR 12935 binding was increased in the hypothalamus and decreased in the striatum. Rats examined 16 h after removal of the pellets showed increased binding in both the hypothalamus and hippocampus.¹¹¹ However, recent research has demonstrated that twice daily escalating doses of morphine for 7 days altered mRNA levels for several dopamine receptors (D_2R and D_3R) but not the DAT in discrete regions of the rat brain.¹¹² Also, post-mortem examination of the striatum of nine chronic heroin users revealed modest reductions in measures of dopamine function but levels of vesicular monoamine transporters were comparable to controls.¹¹³

6.1.2.4 Phencyclidine

Both systemic and local infusions of phencyclidine (PCP) enhance extracellular DA concentrations in the nucleus accumbens^{114,115} and prefrontal cortex.¹¹⁶ PCP-induced elevations of extracellular DA concentrations may result from both indirect and direct effects on the dopaminergic system. NMDA receptors exert a tonic inhibitory effect upon basal DA release in the prefrontal cortex^{116,117} and in the nucleus accumbens through inhibitory effects on midbrain DA neurons.^{118–120} Thus, PCP antagonism of NMDA receptors¹²¹ may facilitate DA release by decreasing the inhibition of central dopaminergic activity.

PCP also increases calcium-independent [^3H]DA release from dissociated rat mesencephalon cell cultures¹²² and striatal synaptosomes.¹²³ PCP has been found to be a potent inhibitor of [^3H]DA uptake in rat striatum,^{124–127} to competitively inhibit binding of [^3H]BTCF, a PCP derivative and

potent DA uptake inhibitor in rat striatal membranes,¹²⁸ and to inhibit [³H]cocaine binding.¹²⁹ In addition, (*trans*)-4-PPC, a major metabolite of PCP in humans,¹³⁰ inhibits [³H]DA uptake in rat striatal synaptosomes with comparable potency to PCP and thus it may be involved in the psychotomimetic effects of PCP.¹²⁴ Recently it was reported that PCP exerts some direct actions at the DAT in the primate striatum using positron emission tomography. Moreover, it was suggested that GABA may also modulate PCP-induced augmentation of DA in the primate striatum.¹³¹

Despite the profound effect PCP exerts on mesolimbic DA activity, evidence suggests that the reinforcing properties of PCP are not dopamine dependent. Carlezon and Wise¹³² have reported that rats will self-administer PCP into the ventromedial region of the nucleus accumbens, as well as NMDA receptor antagonists that do not inhibit DA reuptake. Co-infusion of the DA antagonist sulpiride into the nucleus accumbens inhibits intracranial self-administration of nomifensine, but not PCP. Moreover, rats self-administer PCP into the prefrontal cortex, an area that will not maintain self-administration of nomifensine.¹³³ Therefore, the reinforcing effects of PCP in the nucleus accumbens and prefrontal cortex appear to be related to PCP blockade of NMDA receptor function rather than its dopaminergic actions. Instead, PCP-induced elevations of extracellular DA may mediate other behavioral effects of PCP, such as its stimulant effects on locomotor activity.¹³⁴ The differential effects on locomotor activation of PCP and cocaine do not appear mediated through direct action at the DAT.¹³⁵

6.1.2.5 Marijuana

Recent progress has greatly expanded our knowledge of the endocannabinoid system and the ways in which Δ^9 -tetrahydrocannabinol (Δ^9 -THC), the primary psychoactive component of marijuana, acts upon this system. Advances have included the identification of central cannabinoid receptors (CB₁) as abundant primarily presynaptic G protein-coupled receptors sensitive to endogenous transmitters (anandamide, 2-AG) that function as retrograde transmitters and alter presynaptic neurotransmitter release.¹³⁶ The identification of synthetic ligands that act as agonists and antagonists at the CB₁ receptor has also greatly furthered our understanding of the endocannabinoid system and the effects of Δ^9 -THC in the brain.¹³⁷

Activation of dopaminergic circuits known to play a pivotal role in mediating the reinforcing effects of other abused drugs also results from cannabinoid administration.¹³⁸ Systemic or local injections of Δ^9 -THC enhance extracellular dopamine concentrations in the rat prefrontal cortex,^{139,140} caudate,¹⁴¹ nucleus accumbens,^{142,143} and ventral tegmental.^{144,145} In addition, Δ^9 -THC augments both brain stimulation of reward and extracellular DA concentrations in the nucleus accumbens in Lewis rats, linking dopaminergic activity with the rewarding properties of marijuana.¹⁴³

Recent research is beginning to define the interactions between DA and endocannabinoids in regions critical for our understanding of the reinforcing effects of Δ^9 -THC. Activity-dependent release of endocannabinoids from the ventral tegmental area appears to serve as a regulatory feedback mechanism to inhibit synaptic inputs in response to DA neuron bursting and thus regulating firing patterns that may fine-tune DA release from afferent terminals.¹⁴⁶ Similarly, DA neurons in the prefrontal cortex have been suggested to release endocannabinoids to shape afferent activity and ultimately their own behavior.¹⁴⁷ Research has also begun to shed light on the intracellular signaling pathways activated by THC. Acute administration of Δ^9 -THC produces phosphorylation of the mitogen-activated protein kinase/intracellular signal-regulated kinase (MAP/ERK) in the dorsal striatum and nucleus accumbens. This activation, corresponding to both neuronal cell bodies and the surrounding neuropil, is blocked by pretreatment with DA D₁, and to a lesser extent DA D₂ and NMDA glutamate, antagonists.¹⁴⁸ Given that ERK inhibition was found to block conditioned place preference for Δ^9 -THC, these findings suggest dopaminergic influence of Δ^9 -THC intracellular effects is important for the rewarding effects of Δ^9 -THC.¹⁴⁸

Facilitation of dopaminergic activity by Δ^9 -THC may result from multiple mechanisms. Δ^9 -THC increases DA synthesis¹⁴⁹ and release¹⁵⁰ in synaptosomal preparations. In addition, using *in vivo*

techniques, Δ^9 -THC has been reported to augment potassium-evoked DA release in the caudate¹⁴¹ and increase calcium-dependent DA efflux in the nucleus accumbens.¹⁴² However, whereas Δ^9 -THC produces a dose-dependent augmentation of somatodendritic DA release in the ventral tegmental area, it fails to simultaneously alter accumbal DA concentrations.¹⁴⁴ Because local infusions of Δ^9 -THC through a microdialysis probe did elevate nucleus accumbens DA concentrations, modulation of DA activity in the nucleus accumbens is likely to result from presynaptic effects.

Δ^9 -THC also acts directly at the DAT to affect DA uptake. At low concentrations Δ^9 -THC stimulates uptake of [³H]DA in synaptosomal preparations of rat brain striatum and hypothalamus.¹⁵⁰ Similarly, mice injected with Δ^9 -THC showed increased [³H]DA uptake into striatal synaptosomes and, to a greater extent, in cortical synaptosomes.¹⁵¹ At higher concentrations Δ^9 -THC inhibits uptake of [³H]DA in rat striatal^{150,152,153} and hypothalamic¹⁵⁰ synaptosomes. Also consistent with the hypothesis that Δ^9 -THC blocks DA uptake, using *in vivo* electrochemical techniques, it has been reported that Δ^9 -THC and the DA-reuptake blocker nomifensine produce identical augmentation of voltammetric signals corresponding to extracellular DA.¹⁴¹ While Δ^9 -THC has a similar biphasic effect on norepinephrine uptake in hypothalamic and striatal synaptosomes¹⁵⁰ and increases uptake of 5-HT and GABA in cortical synaptosomes,¹⁵¹ the psychoactive effects of Δ^9 -THC are most likely related to dopaminergic activity because less potent and nonpsychoactive THC derivatives show much less effect on DA uptake than does Δ^9 -THC.¹⁵¹ It is only recently that the effects of Δ^9 -THC exposure on human DAT levels have been examined and while it appears that post-mortem DAT levels in the caudate of individuals with schizophrenia may be influenced by Δ^9 -THC, this result may be of limited generalizability given that people suffering schizophrenia tend to show reduced DAT levels regardless of history of THC use.¹⁵⁴

Δ^9 -THC clearly has profound effects on dopaminergic activity in areas important to the maintenance of the reinforcing effects of other abused compounds. Research relating the persistence of Δ^9 -THC-induced ventral tegmental DA neuron firing in animals chronically treated with Δ^9 -THC to the lack of tolerance to marijuana's euphoric effects further bolsters this link.¹⁵⁵ The ability of Δ^9 -THC to facilitate intracranial electrical self-stimulation in the median forebrain bundle has long been established,¹⁵⁶ however, only recently have the reinforcing effects of Δ^9 -THC been clearly demonstrated using conditioned place preference^{148,157} and drug self-administration^{157,158} procedures. With advances in our understanding of the endocannabinoid system and the further establishment of animal models of Δ^9 -THC-induced reinforcement, increased understanding of marijuana's abuse liability can be expected in coming years. The observation that CB₁ receptor antagonism attenuates the reinstatement of heroin self-administration has also implicated the endocannabinoid system in the mechanisms underlying addiction and suggests a potential therapeutic niche for cannabinoid ligands.¹⁵⁹

6.1.2.6 Ethanol

Ethanol also alters the dopaminergic system. Administration of ethanol has been shown to release DA *in vivo*^{160–162} and *in vitro*.^{163–171} The mechanism(s) by which ethanol increases brain DA levels are slowly beginning to be understood and may involve modulation of DAT activity. Tan et al.¹⁷² examined [³H]DA uptake in brain synaptosomes prepared from rats in various stages of intoxication. [³H]DA uptake was inhibited by ethanol for as long as 16 h following the withdrawal of ethanol. A potential mechanism by which ethanol might work to increase DAT function may involve regulation of DAT expression on the cell surface as [³H]DA has been shown to accumulate following ethanol administration in human DAT expressing *Xenopus* oocytes in parallel with cell surface DAT binding measured by [³H]WIN 35,428.¹⁷³ Moreover, sites on the second intracellular loop of the DAT have been identified that appear important for ethanol modulation of DAT activity.¹⁷⁴ However, further research on the effects of ethanol on DAT function is needed given that recent research suggests acute ethanol attenuates DAT function in rat dorsal striatum and ventral striatum of anesthetized rats and tissue suspensions.¹⁷⁵

Ethanol also increased both spontaneous release and Ca^{2+} -stimulated release of DA, but decreased the amount of K^{+} -stimulated released DA in rat striatum.^{160,172} The increased amount of DA release is not due to nonspecific disruption of the neuronal membrane because acetylcholine levels are not altered.¹⁶² Thus, it appears that ethanol can affect both the release and reuptake of DA via a specific mechanism. However, research investigating ethanol-induced DA release in rat nucleus accumbens slices suggests the mechanism is different from that underlying the effects of depolarization with electrical stimulation or high potassium levels and implicate nonexocytotic mechanisms.¹⁷⁷ Using no net flux microdialysis methodology to examine the effects of intraperitoneal injections of ethanol-induced increases in DA in the rat nucleus accumbens, it was suggested the primary mechanism by which ethanol augments extracellular DA levels is by facilitating release from terminals rather than by blocking the DAT.¹⁷⁸ However, research showing attenuated ethanol preference and consumption in female DAT knockout mice suggests ethanol's action on DAT may be relevant to ethanol-induced reward.¹⁷⁹

A transesterification product of ethanol and cocaine has been discovered. Benzoylcegonine ethyl ester or cocaethylene was first described by Hearn et al.¹⁸⁰ Cocaethylene possessed similar affinity for the DAT as cocaine and also inhibited DA uptake^{180–183} and increased *in vivo* DA levels.^{185,185} Cocaethylene has lower affinity for the serotonin transporter than cocaine. Cocaethylene produces greater lethality in rats, mice, and dogs than cocaine^{186–189} and may potentiate the cardiotoxic effects and tendency toward violence from cocaine or alcohol in humans.¹⁹⁰ While showing a similar pharmacological and behavioral profile as cocaine, cocaethylene appears less potent than cocaine in human subjects.¹⁹¹ Anecdotal reports from human addicts and experimental results with animal subjects support the hypothesis that alcohol is often ingested with cocaine in order to attenuate the negative aftereffects of cocaine.¹⁹²

6.1.2.7 Nicotine

Nicotine increased DA levels both *in vivo*^{11,193} and *in vitro*.^{194–196} Nicotine¹⁹⁷ and its metabolites¹⁹⁸ were found to both release and inhibit the reuptake of DA in rat brain slices, with uptake inhibition occurring at a lower concentration than that required for DA release. In addition, the (–) isomer was more potent than the (+) isomer.¹⁹⁷ However, the effects of nicotine upon DA release and uptake were only apparent when brain slices were utilized because nicotine was unable to affect DA when a synaptosomal preparation was utilized.¹⁹⁷ These results indicate that nicotine exerts its effects upon the DAT indirectly, most likely via nicotine acetylcholine receptors. This finding was supported by the results of Yamashita et al.¹⁹⁹ in which the effect of nicotine on DA uptake was examined in PC12 and COS cells transfected with rat DAT cDNA. Nicotine inhibited DA uptake in PC12 cells that possess a nicotine acetylcholine receptor. This effect was blocked by the nicotinic antagonists hexamethonium and mecamylamine. Additionally, nicotine did not influence DA uptake in COS cells, which lack nicotinic acetylcholine receptors.

Interestingly, a series of cocaine analogues that potently inhibited cocaine binding also inhibited [^3H]nicotine and [^3H]mecamylamine binding.²⁰⁰ It was concluded that the inhibition by these cocaine analogues involves its action on an ion channel on nicotinic acetylcholine receptors. Recently several studies have further investigated the ability of nicotine to regulate DAT function. In slices from rat prefrontal cortex, but not the striatum or nucleus accumbens, nicotine enhances amphetamine-stimulated [^3H]DA release via the DAT. Moreover, the nicotinic acetylcholine receptors responsible for mediating amphetamine-induced [^3H]DA release in the prefrontal cortex were found to be at least partially localized on nerve terminals.^{201,202} However, nicotine was found to augment DA clearance in the striatum and prefrontal cortex in a mecamylamine-sensitive manner, suggesting nicotinic acetylcholine receptors also modulate striatal DAT function.²⁰³ Chronic nicotine and passive cigarette smoke exposure increase DAT mRNA in the ventral tegmental area in the rat²⁰⁴ and other data suggest that changes in DAT numbers following repeated nicotine exposure may be behaviorally relevant since increases in DAT and D_3 receptors in the

nucleus accumbens appear to be at least partially responsible for gender differences in behavioral sensitization to nicotine.²⁰⁵

6.1.3 Abused Drugs and Genetic Polymorphism of the Dopamine Transporter

Familial, twin, and adoption studies suggest there may be a genetic predisposition toward drug addiction.²⁰⁶ Genetic polymorphisms across several neurotransmitter systems, including the dopaminergic system, have been linked to the development of drug addiction.²⁰⁷ In humans the DAT gene (DAT1) has a variable number of tandem repeats (VNTR) in the 3'-untranslated region known to influence gene expression.²⁰⁸ Most research suggests the longer 10-repeat allele yields greater DAT1 expression than the 9-repeat allele.²⁰⁹ According to the reward deficiency syndrome hypothesis alterations in various combinations of genes, including DAT1, may provide some individuals with an underactive reward system and increase the likelihood that they will seek stimulation from the environment including stimulation from abused drugs.²¹⁰

Research has implicated DAT polymorphisms to numerous effects of addictive drugs and addictive liability. Cocaine users with the 9/9 and 9/10 genotypes appear more susceptible to cocaine-induced paranoia than those with the 10/10 genotype.²¹¹ Recently Lott et al.²¹² reported that healthy volunteers with the 9/9 genotype have a diminished responsiveness to acute amphetamine injections on measures of global drug effect, feeling high, dysphoria, anxiety, and euphoria. These results may be significant given a diminished response to alcohol has been linked to future development of alcoholism.²¹³ However, another study found no significant associations between DAT polymorphism and clinical variations in a population of methamphetamine abusers.²¹⁴ Genetic polymorphisms across opioid and monoaminergic systems have also been linked to the development of opiate addiction.²¹⁵ Genetic polymorphisms in both the SERT and the DAT were found to be related to opiate addiction.²¹⁶ Homozygosity at the serotonin transporter (especially 10/10) was related to the development of opiate addiction whereas the genotype 12/10 appeared to be protective against opiate addiction. The DAT1, genotype 9/9 was associated with early opiate addiction. Opiate abuse under the age of 16 was also predicted by a combination of the serotonin transporter genotype 10/10 and the DAT1 genotype 10/10.²¹⁶ Studies have also begun to assess whether the risk of alcoholism may be mediated by genetic polymorphism in a variety of genetic targets, including the dopaminergic system, although conflicting results remain to be clarified. According to some research DAT polymorphism has not clearly been identified as a risk factor for the development of alcoholism,²¹⁷ but it has been associated with the development of severe alcohol withdrawal symptoms.²¹⁸ However, other research has suggested that DAT polymorphism is related to the development of alcoholism but not alcohol withdrawal.²¹⁹ The role of DAT polymorphism in nicotine addiction has received the most attention. Although there have been some conflicting reports,²²⁰ most studies suggest the 9-repeated allele of the DAT is related to a decreased likelihood of being a smoker, a lower likelihood of smoking initiation prior to age 16, and longer periods of abstinence among smokers.^{221–223} This latter finding is consistent with the reward deficiency syndrome hypothesis since individuals with the 9-repeated allele would be expected to have decreased DAT expression leading to higher levels of intracellular DA and therefore a reduced need for novelty and external reward including cigarettes. Clearly genetic polymorphism across a number of neurotransmitter systems plays a role in the development of drug addiction. However, several studies now implicate genetic variation at DAT as being a potential contributor to this mixture.

6.1.4 Conclusions

The dopaminergic system plays a role in the abuse liability for some, if not most, drugs. The stimulants, opiates, marijuana, nicotine, and ethanol, all interact directly or indirectly with the dopaminergic system, and most of these have actions on the DAT (Table 6.1.4). Numerous lines of evidence suggest the positive reinforcement, or DA hypothesis, of addiction falls short in

Table 6.1.4 Comparison of the Self-Administration of Various Drugs and the Effect That Drug Has on DAT

Drug	Self-Administered	Increases DA via DAT	Ref.
Cocaine	+	+	27, 28, 224
Amphetamine	+	+	78, 224
MDMA	+	+	73, 225
DMT	?	—	226

Marijuana	+	+	150, 157, 158
PCP	+	+	124–127, 235

accounting for all aspects of addiction.²³⁶ While many believe the elevation of DA within the mesolimbic DA system is a contributing factor to the abuse liability of drugs, considerable evidence supports the notion that neuroadaptive changes resulting from chronic drug use is what actually drives addictive behavior.²³⁷ An understanding of the role of the DAT in the addictive process will likely involve the understanding of how drugs initially interact with the DAT as well as the effects of chronic drug exposure on DAT expression and function.

DAT occupancy alone does not impart a drug with addictive properties. Some drugs that interact with the DAT, such as cocaine, are quite addictive, while other drugs, such as mazindol, are not. There appears to be a temporal component in that, while mazindol interacts with the dopaminergic system, its entry into the brain is slow compared to that of cocaine.^{56,57} The importance of the rate at which transporter occupancy occurs is also underscored by the observation that routes of drug administration, like smoking or intravenous injection, that lead to rapid entry into the brain, and for some drugs rapid DAT occupancy, are more likely to produce an intense “high” and have greater addictive potential than drug administration via oral or nasal routes, which are associated with delayed drug action in the brain.^{238,239} In addition, baseline DA activity within the mesolimbic pathway may also be an important influence on psychostimulant-induced “high.” The subjective high produced by methylphenidate appears related to both DAT occupancy and basal DA activity of the subject.^{240,241} This result hints at the potential importance of genetic polymorphism within the dopaminergic system on addictive liability. Given that genetic polymorphism of the DAT has been tentatively linked to the addictive potential of several drugs, a better understanding of the contribution that genetic polymorphism of the DAT plays in the development of addiction will be valuable.

The cloning of the DAT^{242,244} and its subsequent transfection into cells have allowed for the study of DAT in much greater detail. Moreover, the development of transgenic mice that lack DAT has now afforded the study of the mechanisms of action for many drugs.⁵⁹ Using these and other powerful new tools, in the future we may be better able to understand the role of DAT in the mechanisms of action for addictive drugs, the addictive process, and individual differences in a person’s predisposition toward drug addiction.

6.2 NEUROCHEMISTRY OF NICOTINE DEPENDENCE

Darlene H. Brunzell, Ph.D.

Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut

Tobacco use is the leading preventable cause of death in North America and a growing medical problem in developing countries throughout the world. In the Western world, the rising cost of cigarettes, social mores, and public policy against smoking have led to appreciable decreases in cigarette use over the last 25 years.^{1,2} In recent years, however, smoking prevalence has appeared to reach asymptote at approximately 25%.^{3,4} Those with schizophrenia, a history of depression, alcoholism or polydrug use, and those who have difficulty quitting with the help of currently available cessation methods continue to smoke.^{3,5} Until recently, there were only two FDA-approved treatments for tobacco cessation: nicotine replacement therapy and bupropion. In May 2006, the FDA approved the use of a nicotinic receptor partial agonist, varenicline, for treatment of tobacco dependence. Whereas these therapies have realized some success, there remains an apparent need for novel treatments for nicotine and tobacco dependence. Nicotine is believed to be a major psychoactive component in cigarettes and smokeless tobacco. Advancing our understanding of the neurochemical mechanisms of nicotine use and how nicotine-associated changes in neurochemistry relate to behaviors that support addiction will not only lead to novel treatments for tobacco cessation, but might also lead to advanced therapies for diseases that have high comorbidity with tobacco use. This chapter reviews nicotinic receptor composition, followed by a systems overview of how various nicotinic receptor subtypes are thought to contribute to nicotine reinforcement and incentive motivational processes. Because nicotine dependence is thought to reflect changes in communication between areas of the brain that control motivation, cognition, and reward, candidate intracellular signaling proteins thought to promote nicotine-dependent neuroplasticity are discussed, and finally the promise of novel compounds for tobacco cessation and their potential clinical applications are discussed.

6.2.1 Nicotinic Receptor Composition

Nicotine action is mediated through the nicotinic acetylcholine receptors (nAChRs). Although slightly different in subunit composition, most of our notions about neuronal nAChR structure and function are derived from exquisite work on nAChRs in the torpedo electric organ and at the neuromuscular junction (for detailed review, see References 6 through 9). Members of the ligand-gated superfamily of receptors, nAChRs respond endogenously to acetylcholine (ACh) in the periphery and central nervous system (CNS).⁶ There are two general classes of nAChRs in the brain, both pentameric in structure. Neuronal nAChRs are either heteropentameres, made up of a combination of five α_2 – α_6 and β_2 – β_4 receptor subunits, or are homomeric in structure, made up of five α_7 subunits (Figure 6.2.1). Each subunit contains an N-terminal agonist binding domain, four transmembrane domains (M1 to M4), a large cytoplasmic loop between M3 and M4, and an extracellular C-terminus.^{10,11} The nAChRs exist in a variety of functional states including a closed, resting state, an open, activated state, a desensitized, unresponsive state, and an irreversible, inactive state.¹² When activated, the M2 domain of the nAChR undergoes a conformational change making the ion pore of the receptor permeable to cations (e.g., Na^+ and Ca^{2+} ;^{10,13,14}) that lead to cellular activation, modification of second messenger signaling, and enhancement of neurotransmitter release.

The nAChR subtypes vary in response to pharmacological manipulation. The α_7 receptors have a low affinity for nicotine and are sensitive to α -bungarotoxin (α -BTX) antagonism whereas the heteromeric nAChRs are not.¹⁴ The β_2 containing (β_2^* ; asterisk denotes the presence of additional subunits) nAChRs have the highest affinity for nicotine binding and some selectivity for antagonism

Figure 6.2.1 Diagram of nicotinic acetylcholine receptor (nAChR) structure. A top view of (A) an α_7 nAChR and (B) a β_2 nAChR shows that homomeric and heteromeric classes of nAChRs are both pentameric in structure. Each subunit is made up of four transmembrane domains with the M2 domain making up the ion pore. (C) A side view of the four transmembrane regions shows the N-terminus, C-terminus, and large M3–M4 intracellular loop that make up each nAChR subunit. The extracellular loops are available for binding to ligands and the intracellular loop is available for regulation of the nAChR by intracellular signaling proteins.

with dihydro-beta-erythroidine (DH β E),¹⁵ and the α_3^* and α_6^* nAChRs are the only subtypes known to respond to α -conotoxin MII.^{16–21} After some period of nAChR stimulation, there are conformational changes in the receptors^{22,23} that cause them to become transiently unavailable for activation by nicotinic agonists,²⁴ sometimes irreversibly.²⁵ This desensitization of the receptors is thought to be regulated by calcium-mediated protein kinases at the intracellular loop between M3 and M4,^{22,26} providing negative feedback to the nAChRs. The variability in sequence homology between nAChR subtypes at the intracellular loop may be responsible for the different rates of desensitization identified for the α_7 and β_2^* nAChRs.^{27–29} Once bound by acetylcholine or nicotinic agonists, nAChR effects on neurochemistry depend on the conformation of the receptor, neuroanatomical localization of the receptor subtype, and the intracellular consequences of nAChR activation.

6.2.2 Neurochemical Systems That Support Nicotine Use

The prevailing belief in the drug addiction field is that with repeated drug use, neuroplasticity occurs within areas of the brain that modulate motivation, impulsivity, and reward.^{30–32} These neurochemical changes are thought to support addictive behaviors and to transform the non-addicted brain into an addicted one. Much of the animal work to date has focused on the neurochemical mechanisms of nicotine reinforcement. Drug reinforcement is not included in the DSM-IV addiction criteria for good reason. A person can enjoy the pleasurable properties of a glass of wine without having any particular risk for alcoholism. If a drug such as nicotine is not positively or negatively reinforcing, however, it will not be sufficiently administered in order for nicotine dependence to develop. In this context, understanding the mechanisms of nicotine reinforcement might help identify genetic vulnerabilities for or protection from developing an addictive phenotype.³³ *Nicotine dependence* is a much more complex behavioral phenomenon. Following repeated use, incentive motivational processes (e.g., craving) come to regulate drug intake even in the absence of drug reinforcement or relief of symptoms of withdrawal.^{34,35} Repeated association of cues with a primary reinforcer, such as nicotine, results in the ability of those cues to reinforce behaviors like drug seeking.¹⁶

6.2.2.1 Nicotine Reinforcement

The Mesocorticolimbic Dopamine System

Like other drugs of abuse, the reinforcing effects of nicotine are modulated, in large part, via the mesocorticolimbic dopamine (DA) system. Animal studies have shown that systemic and ventral tegmental area (VTA) administration of nicotine results in DA release to the nucleus accumbens (NAc).^{36–38} Accumbens DA release increases with repeated nicotine exposure.³⁶ This neuroplasticity, termed sensitization, coincides with nicotine reinforcement^{39–41} and locomotor activating effects of nicotine.^{36,37} Both blockade of VTA nicotinic receptors^{42,43} and destruction of DA inputs to the NAc⁴⁴ greatly reduces nicotine self-administration and conditioned place preference (CPP)[†] in rats. Unlike other psychostimulants, which enhance dopamine release via binding to dopamine transporters, nicotine regulation of dopamine is less direct. Although much evidence suggests that nAChRs act postsynaptically to enhance DA neuron activity,^{45,46} emerging evidence indicates that VTA and NAc nAChRs act presynaptically to modulate neurotransmitter release^{19,28,47} and regulate transporter function.⁴⁸

An accumulation of data suggests that both the β_2^* and α_7 receptor subtypes contribute to nicotine-induced increases in DA release and associated nicotine-dependent behaviors.^{28,39,40,42,43,49,50} In the VTA, α_7 and β_2^* nAChRs, respectively, reside on glutamatergic and GABAergic terminals. Electrophysiological data indicate that the higher affinity β_2^* nAChRs are the first to be activated by nicotine (Figure 6.2.2A). In the VTA slice preparation, the β_2^* nAChRs desensitize very quickly, becoming inactivated.^{28,47} Because β_2^* nAChRs stimulate γ -aminobutyric acid (GABA) release, desensitization of these receptors results in disinhibition of VTA DA neurons. Removal of GABA release on DA neurons is coincident with activation of the lower-affinity α_7 nAChRs, which facilitate excitatory glutamatergic input to the DA neurons (Figure 6.2.2B), resulting in a net increase in DA neuron firing.²⁸ At the DA terminals, however, β_2^* nAChRs ($\alpha_4\beta_2$, $\alpha_6\beta_3\beta_2$, $\alpha_4\alpha_6\beta_3\beta_2$, $\alpha_4\alpha_5\beta_2$) and not α_7 nAChRs support nicotine-stimulated DA release.¹⁹

Studies in knockout mice indicate that the β_2^* nAChRs are necessary for nicotine self-administration, DA-dependent locomotor activation, and nicotine-associated enhancement of NAc DA release.^{40,51–53} Combined with studies showing that antagonism of the high-affinity nAChRs block self-administration,^{44,54} it would appear that β_2^* nAChRs are particularly critical for nicotine reinforcement. Unlike wild-type mice that self-administer both cocaine and nicotine, β_2^* nAChR-null mutant mice learn to self-administer cocaine normally, but stop bar pressing as though receiving saline when cocaine is switched to nicotine.⁴⁰ Self-administration of VTA nicotine and associated DA release is rescued, however, in β_2^* nAChR knockout mice with lentiviral-mediated expression of β_2 subunit DNA in the VTA.⁵⁵ Whereas several configurations of the β_2^* nAChRs exist at the level of the VTA, much data point to the $\alpha_4\beta_2$ nicotinic receptors as playing a primary role in nicotine reinforcement. Mice lacking the α_4^* nAChRs fail to show nicotine-dependent enhancements of DA release,⁵³ and a single nucleotide leucine-to-alanine α_4 mutation in the pore-forming M2 domain renders the α_4^* nAChRs hypersensitive to nicotine stimulation and promotes conditioned place preference at otherwise sub-optimal doses of nicotine.⁵⁶ Together, these data suggest that the β_2^* nAChRs are necessary and the α_4^* nAChRs are sufficient for nicotine reinforcement. Interestingly, the α_4^* nAChR knockout animals but not the β_2 -null mutant mice show an increase in basal DA release to the NAc,^{40,53} indicating that receptor conformations in addition to $\alpha_4\beta_2$ mediate DA input to the NAc.

Another candidate receptor subunit for nicotine reinforcement that has been less studied is α_6 . The α_6 subunit associates with the β_2 , β_3 , and α_4 nAChR subunits in the CNS.^{19,20,57,58} Unlike

[†] Conditioned place preference refers to a Pavlovian learning paradigm in which animals are repeatedly exposed to two novel adjacent chambers, one paired with nicotine administration and the other paired with saline injection. During the test the animal is allowed to cross between compartments. An increased amount of time spent in the drug-paired chamber is thought to reflect drug reinforcement and is defined as conditioned place preference.

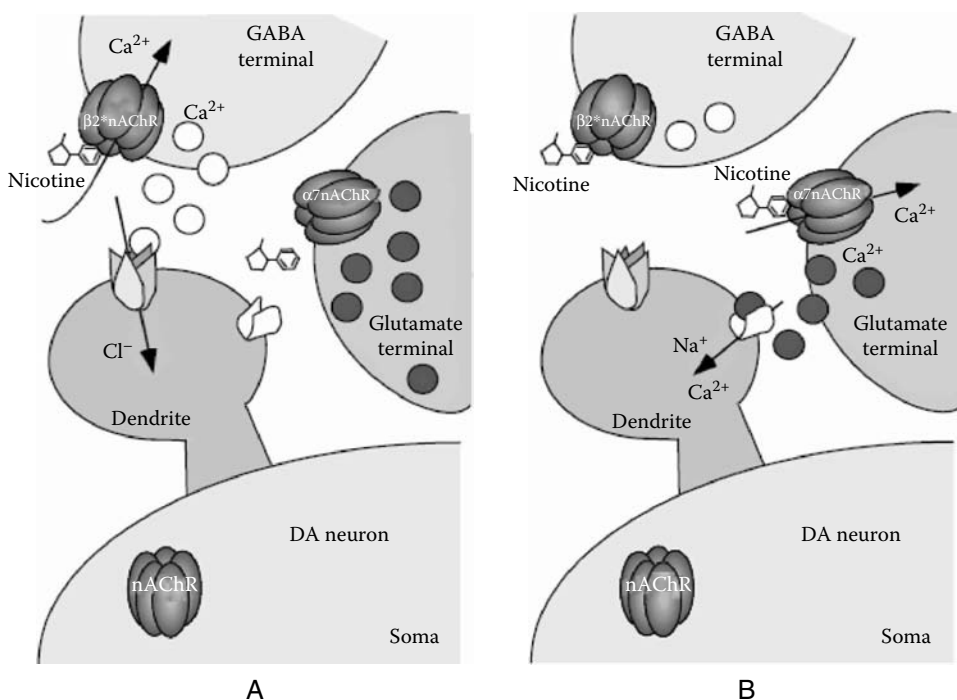

Figure 6.2.2 A presynaptic model of nicotine stimulation of ventral tegmental area DA neurons. (A) Nicotine first binds to the high-affinity β_2 containing nicotinic acetylcholine receptors (β_2 -nAChRs), which reside on neuron terminals that release the inhibitory neurotransmitter GABA. Entry of calcium (Ca^{2+}) through the nAChR ion pore facilitates vesicle docking and neurotransmitter release. (B) The inhibitory GABA input to the DA neurons is short-lived, however, due to a fast desensitization of the β_2 -nAChRs. As nicotine accumulates, it binds to the lower-affinity α_7 nAChRs that reside on the terminals of neurons that release the excitatory neurotransmitter, glutamate. Together nAChR-regulated disinhibition of GABA input and stimulation of glutamate input result in a net elevation of DA neuron activity and DA release in VTA projection areas.

$\alpha_4\beta_2$ nAChRs, which are ubiquitously expressed throughout the brain, α_6 mRNA is chiefly expressed in catecholaminergic nuclei,⁵⁸ with receptor expression on DA terminals in the striatum.⁵⁹ Although no direct link has been made regarding the role of this receptor subunit in nicotine reinforcement, α_6 is well suited to contribute to neuroplasticity associated with nicotine exposure. α_6 -nAChRs are capable of modulating nicotine-associated DA release at striatal DA terminals^{19,57} and are upregulated following chronic nicotine exposure,⁶⁰ suggesting that the α_6 subunit might contribute to nicotine-associated changes in DA release that correlate with locomotor activation and nicotine reinforcement.

As α_7 nAChRs are known to reside on glutamate terminals in the VTA,⁶¹ the role of α_7 nAChRs in nicotine-elicited dopamine release is supported by studies that manipulate glutamate receptor function. Glutamate receptor antagonism in the VTA greatly reduces nicotine-associated increases in NAc DA release without affecting baseline levels of accumbens DA.⁶² Behaviorally, NMDA glutamate receptor antagonism blocks nicotine locomotor sensitization in rats.⁶³ As the reports of α_7 antagonism on nicotine reinforcement are equivocal,^{42,54,64} it is unclear what role the α_7 nAChRs play in nicotine reward. Local administration of 4 nM methyllycaconitine (MLA) into the VTA reverses nicotine-conditioned place preference,⁴² and high doses of this putatively selective α_7 antagonist (3.9 and 7.8 mg/kg i.p.) attenuate nicotine self-administration in rats, suggesting that α_7 nAChRs contribute to nicotine reinforcement.⁶⁴ Similar doses of MLA achieved in brain,⁶⁵ however, block nicotine-stimulated DA release in striatal synaptosome preparations that do not contain α_7 nicotinic receptors,^{19,66} bringing the selectivity of MLA for α_7 nAChRs into question at higher

doses.⁶⁶ The fact that MLA blocks α conotoxin MII binding at behaviorally efficacious doses^{20,67} raises the possibility that antagonism of α_3^* or α_6^* nAChRs in addition to α_7 nAChRs might be responsible for MLA-dependent attenuation of nicotine reinforcement.

Hindbrain Inputs to the VTA

Hindbrain regions including the pedunclopontine tegmental nucleus (PPT) and lateral dorsal tegmental nucleus (LDT) give rise to acetylcholinergic, GABAergic, and glutamatergic projections to the VTA that are thought to regulate drug reward.^{68–70} Local infusion of GABA receptor agonists and lesions to the PPT result in a marked attenuation of nicotine-associated locomotor activation, nicotine CPP, and nicotine self-administration in rodents.^{71–73} PPT administration of DH β E also greatly attenuates nicotine self-administration in rats,⁷² suggesting that PPT-regulated nicotine reinforcement is mediated in part by high-affinity β_2^* nAChRs. Nicotinic receptor antagonism also inhibits ACh release in PPT synaptosome preparation.⁶⁷

Various studies suggest that basal forebrain cholinergic projections and accumbens ACh interneurons may also regulate behavior associated with the reinforcing properties of cocaine, morphine, and ethanol.^{74–78} Whereas muscarinic ACh receptors might also meter behaviors associated with drug reinforcement, studies show that nAChR stimulation enhances and antagonism attenuates cocaine CPP. β_2 -null mutant mice are also slightly impaired at cocaine CPP.⁷⁹ Given that ACh appears to modulate both drug aversion and reward,^{42,76} it is possible that nAChRs in mesolimbic DA areas regulate motivational valence or learning and memory processes that underlie drug use and not drug reinforcement per se. There is very high comorbidity for tobacco use with substance use disorders.³ The specific contributions of nAChRs to drug reinforcement, more broadly defined, remain to be determined.

Beyond the Role of DA in Nicotine Reinforcement

Although the research described thus far supports the tenet that nicotine reinforcement is regulated by the ability of nAChRs to enhance mesolimbic DA release, an accumulation of evidence questions the simplicity of this dogma. Despite treatment with neuroleptics that block DA receptor stimulation, the percentage of people with schizophrenia who smoke is several times greater than the population as a whole.^{3,5} In rats, the effects of intra-VTA infusion of nicotine on behavior are dose dependent; animals display conditioned place aversion at low doses and CPP at steadily increasing doses of nicotine.⁸⁰ The experimenters found that intra-accumbens and systemic administration of the neuroleptic, α -flupenthixol, reversed the conditioned aversive but not rewarding effects of nicotine, concluding that NAc dopamine regulates nicotine aversion and not reward.⁸⁰ α -Flupenthixol, however, blocks both Gs-coupled, D₁- and Gi-coupled, D₂-type DA receptors, which are known to have opposite effects on the cAMP signaling pathway (Figure 6.2.3).³¹ Recent evidence suggests that cAMP-responsive element-binding protein regulates both rewarding and aversive effects of morphine.⁸¹ Together these data suggest that NAc DA and the cAMP pathway might serve to regulate motivational valence rather than drug reinforcement per se.

Electrophysiological data show that while pulses of ACh enhance DA neuron activity as one might expect with acute nicotine exposure, simulation of steady states of human nicotine concentrations⁸² quickly result in desensitization of the midbrain nAChRs.⁴⁷ Indeed, striatal synaptosome preparation used to measure DA release show that much lower doses of nicotine are required for desensitization than for activation of nAChRs.^{24,83} This acute tolerance might account for smoker reports that the first cigarette of the day is most pleasurable.⁸⁴ In human brain, β_2^* nAChR binding is prolonged for as long as 5 h after a smoking episode,⁸⁵ begging the question as to why people continue to smoke throughout the day. Research using electrochemical cyclic voltammetry shows that nAChR regulation of DA release depends upon the state of the DA neuron during

Figure 6.2.3 Mechanisms by which nicotine might affect ERK and CREB signaling. Nicotine stimulation of glutamate release or direct activation of nicotinic acetylcholine receptors (nAChRs) results in the influx of calcium (Ca^{2+}), among other cations, through NMDA glutamate and nAChRs. Intracellular Ca^{2+} can result in activation of Ca^{2+} /calmodulin-dependent protein kinases that lead to phosphorylation and activation of the transcription factor, cAMP-responsive element binding protein (CREB). Nicotine-associated changes in levels of growth factors result in changes in activation of neurotrophic receptors that stimulate extracellular regulated protein kinase (ERK) and downstream activation of CREB via protein kinases, ribosomal S6 kinase (Rsk) and mitogen- and stress-activated protein kinase (Msk). *In vitro* studies show that fast activation of ERK by nicotine is Ca^{2+} -dependent and mediated via voltage-gated Ca^{2+} channels;^{119,120} however, the intracellular mechanism of Ca^{2+} -mediated ERK activation remains to be determined. Nicotine-stimulated elevations of DA release can lead to activation of G protein-coupled receptors, which in turn modify cAMP signaling and downstream activation of protein kinase A (PKA), a kinase known to directly phosphorylate CREB and promote CRE mediated transcription.

nicotine application.^{86,87} When DA neurons are held in a tonic or “resting” state, nicotine decreases DA release, but when DA neurons are in a phasic state, as one would expect during the presentation of a reward,⁸⁸ nicotine enhances DA release.⁸⁶ Interestingly, DA neurons respond similarly to nicotine and nAChR antagonists, suggesting that nicotine’s action on DA release is mediated by desensitization of the receptor.^{86,87} Over time, cues come to elicit phasic activity of DA neurons where primary reinforcers once did.⁸⁸ These data may explain at an electrophysiological level how cigarette-associated cues maintain smoking behavior.

6.2.2.2 Neurochemistry of Cue-Driven Behaviors

Although the NAc has received the most attention for its role in nicotine reinforcement, other VTA projection areas including the hippocampus, prefrontal cortex, and amygdala contribute to the control that cues have over behavior, or conditioned reinforcement.^{30,32} Such behaviors may represent changes in incentive motivation that perpetuate drug use even in the absence of drug reinforcement.³⁴ Sensory cues associated with the act of inhaling regulate the degree to which smokers find pleasure in smoking denicotinized cigarettes.^{89,90} The VTA, NAc, amygdala, and prefrontal cortex are activated in humans during craving and the presentation of cigarette-associated cues,^{91,92} indicating that these areas of the brain contribute to conditioned reinforcement associated with cigarette smoking.

Figure 6.2.4 A perpetual learning model for nicotine dependence. Evidence shows that cues greatly enhance nicotine self-administration and that nicotine exposure augments conditioned reinforcement for natural and drug reinforcers. Although drug reinforcement does not necessarily lead to addiction, nicotine reinforcement most likely facilitates the development of nicotine dependence. Evidence suggests that the β_2^* , α_4^* , and α_7 nicotinic acetylcholine receptors (nAChRs) and metabotropic glutamate receptor 5 (mGluR5) glutamate receptors contribute to nicotine self-administration. The D₃ dopamine receptors (D3 DAR), CB₁ cannabinoid receptors (CB1R), mGluR5 glutamate receptors, and the transcription factor CREB appear to be involved in cue-associated changes in neuroplasticity and the control of nicotine-paired cues over nicotine-dependent behaviors. Nicotine-associated enhancement of conditioned reinforcement for cues paired with a natural reinforcer requires β_2^* nAChRs. β_2^* nAChRs might also serve to amplify the conditioned reinforcement properties of nicotine-associated cues.

Animal studies have shown that cues greatly enhance the degree to which animals will self-administer nicotine^{34,93–95} and can support self-administration behavior for weeks after the removal of nicotine.^{93,96} In rats, a nicotine-associated cue is a more efficient primer than nicotine itself at reinstating self-administration,⁹⁷ and a nicotine-paired context can elicit changes in immediate early gene activity in the prefrontal cortex,⁹⁸ suggesting that conditioned reinforcement for nicotine-associated cues occurs at a molecular level. Like other drugs of abuse, the control of nicotine-associated cues over behavior is likely mediated within areas of the brain that receive DA and glutamate stimulation.³² One theory suggests that coincident activation of NAc neurons by DA and glutamate supports drug reinforcement and natural reward.⁹⁹ Blockade of metabotropic glutamate receptor 5 (mGluR₅) with the antagonist MPEP not only decreases nicotine self-administration and break points for nicotine,^{100,101} but also significantly attenuates cue-induced reinstatement of nicotine self-administration.¹⁰² Disruption of D₃ DA receptors, which are upregulated with repeated nicotine exposure,¹⁰³ significantly attenuates behavioral locomotor sensitization in response to a nicotine-paired context.¹⁰⁴ D₃ antagonists and partial agonists also block nicotine-conditioned place preference¹⁰⁵ suggesting that manipulation of D₃ receptors might be efficacious in reducing nicotine seeking or nicotine reinforcement. The efficacy of D₃ partial agonists and antagonists in blocking nicotine self-administration remains to be tested, however.

Not only do cues control nicotine use, but nicotine exposure also enhances conditioned reinforcement in rats and mice for weeks following exposure to nicotine^{106–109} (Figure 6.2.4), and can act as an occasion setter to facilitate the association of cues with reward.¹¹⁰ Studies in β_2 -null mutant mice show that nicotine enhancement of conditioned reinforcement is dependent on the presence of the β_2^* nAChRs.¹⁰⁶ The cannabinoid receptor 1 (CB₁) antagonist, rimonabant, appears to curb both primary and incentive motivation processes affected by nicotine,¹⁰⁶ blocking control of conditioned reinforcers over nicotine intake and having potential to decrease weight gain associated with quit attempts.¹¹¹ Nicotine's ability to act as a primary reinforcer in addition to its ability to enhance learning and incentive motivational processes may explain why people and animals have difficulty abandoning behaviors associated with tobacco smoking and nicotine intake.

6.2.3 Nicotine-Associated Changes in Intracellular Signaling

At the cellular level, nicotine-induced changes in second messenger signaling are thought to support nicotine-associated changes in neurochemistry and behavioral phenotypes. Due to their putative roles in cellular processes underlying learning and memory (for detailed review, see References 112 and 113), the extracellular regulated protein kinase (ERK) and cyclic AMP responsive element binding (CREB) signaling pathways have received the most attention for their potential roles in neuroplasticity underlying nicotine dependence (Figure 6.2.3).^{114–117} *In vitro* studies have shown that ERK is activated by nicotine treatment¹¹⁸ and is critical for nicotine-dependent activation of CREB^{119,120} and tyrosine hydroxylase, the rate-limiting enzyme in DA synthesis.^{121,122} *In vivo* studies show that regulation of ERK by nicotine is region and treatment specific.^{114,116} Although acute administration of nicotine elevates levels of phosphorylated ERK (pERK) in the amygdala and prefrontal cortex,¹¹⁶ chronic exposure to doses of nicotine known to have relevance for neural plasticity and locomotor activation^{52,123} results in elevation of pERK in the prefrontal cortex, but leads to significant decreases in levels of ERK and pERK in the amygdala.¹¹⁴ Amygdala changes in ERK protein expression following repeated nicotine exposure may support conditioned reinforcement processes; however, the role of ERK signaling in incentive motivation remains to be explored.

An accumulation of evidence suggests that the transcription factor CREB regulates the rewarding properties of nicotine. Unlike their wild-type counterparts, mice with a targeted mutation of CREB (CREB^{α0}) fail to show nicotine-conditioned place preference following four pairings of a novel chamber with nicotine.¹¹⁷ In wild-type mice, acute and four repeated exposures to nicotine both resulted in elevated levels of VTA pCREB,¹¹⁷ suggesting that activation of CREB in the VTA might regulate the primary reinforcing properties of nicotine. Interestingly, the nicotine-paired chamber was also capable of eliciting an increase in pCREB,¹¹⁷ showing that the nicotine-paired environment became a conditioned reinforcer capable of controlling intracellular signaling associated with nicotine exposure. Chronic and acute nicotine exposure and nicotine withdrawal have been shown to affect phosphorylation of CREB in the NAc, PFC, VTA, and amygdala.^{114,115,117} NAc levels of pCREB differ between acute paradigms, where little to no change is observed,^{114,117,124} and chronic exposure where marked decreases in NAc pCREB are evident.¹¹⁴ Similarly, increases of pCREB in the prefrontal cortex are specific to chronic nicotine exposure in mice¹¹⁴ and are observed to decrease in rats following nicotine withdrawal,¹¹⁵ suggesting that CREB in the NAc and prefrontal cortex might regulate some conditioned emotive properties of nicotine reward or withdrawal. Nicotine withdrawal can precipitate an episode of depression¹²⁵ and inhibition of NAc CREB has antidepressant-like effects in rats.¹²⁶ More studies need to be done to clarify the contributions of the prefrontal cortex and NAc CREB in complex behaviors that support nicotine dependence.

6.2.4 Summary and Clinical Implications

Nicotine dependence is a complex biobehavioral phenomenon that is likely regulated by cue-driven incentive motivational processes. As suggested by the work described here, antagonism at mGluR₅ glutamate, D₃ DA, CB₁ cannabinoid, and β₂*nAChRs might have particular promise for promoting nicotine cessation. Preliminary trials indicate that quit rates for β₂*nAChR partial agonist varenicline are twice that reported for more traditional therapies.¹²⁷ Preclinical evidence suggests that even greater nicotine cessation outcomes might be achieved if varenicline is used in combination with behavioral therapies. If administered using techniques that enable local control of expression, CREB and ERK might serve as effective molecular targets for gene therapy. Other novel nicotine-cessation treatments under consideration include those that reduce the function of mu opioid receptors in the brain. Evidence suggests that naltrexone, an opiate antagonist that has enjoyed some success as a treatment for alcohol cessation,¹²⁸ should be considered for “off-label” nicotine cessation use.^{129–131} Mu opioid receptors in the VTA appear to promote nicotine reward¹¹⁷ and may be one point of convergence for nicotine and alcohol abuse potential. Last, a nicotine vaccine that

limits the bioavailability of nicotine in the brain has been shown to lead to significant reductions in nicotine intake in preclinical trials.¹³²

Despite that a large number of smokers want to quit, few are able to do so with currently approved treatments for nicotine dependence. Among those who have particular difficulty quitting smoking are those who suffer from polydrug use, depression, and schizophrenia.^{3,5} There is large individual variability in responsiveness to nicotine and reasons for smoking.⁸⁴ Parsing out the specific contributions of nAChRs and their downstream neurochemical targets to various behaviors that support nicotine dependence may lead to treatments for nicotine cessation that are effective in a broader spectrum of individuals.

6.3 NEUROCHEMICAL SUBSTRATES OF HABITUAL TOBACCO SMOKING

Irina Esterlis, Ph.D., Suchitra Krishnan-Sarin, Ph.D., and Julie K. Staley, Ph.D.

Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut and VA Connecticut Healthcare System, West Haven, Connecticut

Tobacco is the most widely abused substance in our society today. Not only are cigarettes highly addictive and the source of a multitude of social, economic, and medical consequences, but also their abuse is most prevalent among psychiatric populations, including persons afflicted with schizophrenia, bipolar, major depressive, anxiety, and substance abuse disorders. Cigarette smoking kills more Americans than accidents, alcoholism, fires, illegal drugs, AIDS, murder, and suicide combined, and is responsible for approximately 400,000 premature deaths per year in the U.S. and 4.83

million premature deaths per year worldwide.¹ The medical, social, and economic consequences of cigarette smoking cost the U.S. society approximately \$100 billion annually.² Despite the overwhelming evidence of the medical risks associated with cigarette smoking, about 20% of the U.S. population continues to smoke. These devastating costs to society underscore the need for research into the neurochemical mechanisms underlying the development and maintenance of the addiction to cigarette smoking. By understanding the neurochemical substrates promoting the addiction to cigarettes, better treatments for this destructive and costly brain disorder may be developed.

6.3.1 Cholinergic Adaptations in Smokers

The nicotinic acetylcholine receptor (nAChR) is the initial site of action of nicotine. With the advent of *in vivo* imaging methods, such as single photon emission computed tomography (SPECT), the amount of nicotine occupying nAChR in brain after smoking a cigarette may be measured. The occupancy of nAChR containing the β_2 -subunit by nicotine after smoking one and two cigarettes has recently been determined using the nicotinic agonist radioligand [123 I]5-IA-85380 and SPECT. Occupancy of β_2 -nAChR after smoking one cigarette ranged from 34 to 62%, while, after two cigarettes, the range was from 35 to 56%, both in a region-dependent manner. Interestingly, nicotine continually occupied β_2 -nAChR 1.8 to 6 h after smoking a cigarette even in the presence of continued radiotracer infusion (see Figure 6.3.1). The long-lasting occupancy of the β_2 -nAChR by nicotine raises important questions about the frequency of cigarette smoking. Specifically, why do smokers smoke cigarettes every 1 to 2 h if the receptor remains occupied by nicotine, a pharmacologically active metabolite or endogenous acetylcholine for up to 6 h after smoking? One hypothesis is that the long-lasting occupancy may render this subset of receptors inactive, thus promoting the upregulation of receptors and agonist-binding sites as has been noted in post-mortem brain and peripheral lymphocytes from smokers. [3 H]nicotine binding is higher in peripheral blood cells of smokers vs. nonsmokers and, interestingly, correlates with the number of cigarettes smoked per day.³ [3 H]nicotine binding is higher in the gyrus rectus (Brodmann area 11), hippocampus, thalamus, midbrain,^{4,5} striatum, entorhinal cortex, and cerebellum,⁶ and [3 H]epibatidine binding is higher in prefrontal and temporal cortex and hippocampus⁷ in post-mortem brain from human

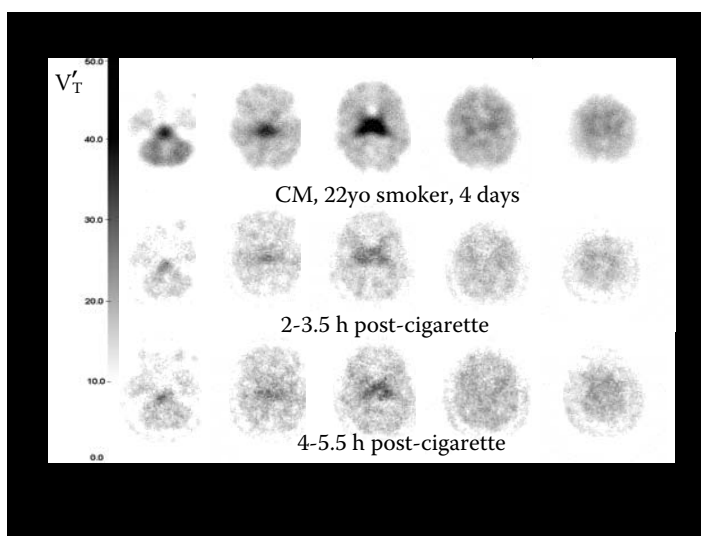

Figure 6.3.1 Transaxial parametric images in units of V_T' show regional [123 I]5-IA binding to β_2 -nAChR prior to and 2 to 3.5 h and 4 to 5.5 h after smoking a single cigarette. The bar at the right illustrates shades of gray corresponding to V_T' values.

smokers. Studies in animals treated chronically with nicotine have demonstrated that the upregulation in nAChR is due solely to the effects of nicotine.^{8,9}

The mechanism of the upregulation in nicotine binding sites is not well understood. It has been established that, in contrast to the classic pharmacological dogma, which states that a desensitized receptor has lower affinity for agonists, the desensitized inactivated nAChR¹⁰ exhibits higher binding affinity for agonists compared to the closed "resting" state and the open "activated" state.¹¹ When an endogenous agonist (e.g., acetylcholine), or an exogenous agonist (e.g., nicotine) binds to β_2 -nAChR in its closed "resting" state, the channel undergoes a conformational change to the "open" state where ions influx. Subsequently, the ion channel undergoes a second conformational change to the "desensitized" state that corresponds to the closing of the channel. With prolonged desensitization, the β_2 -nAChR enters an "inactivated" state.¹² The state of nAChR receptor is determined by agonist concentration, and the time course of agonist administration.¹¹ It is well established that the agonist-induced conformational change of the nAChR to the desensitized state occurs rapidly (i.e., within milliseconds).¹³ However, in animals the nAChR upregulation has been mapped at time points only as early as 7 to 24 h post-nicotine.^{14,15} Thus, while it is known that the desensitized state of the receptor exhibits higher affinity for agonist that may give an appearance of an acute increase in β_2 -nAChR, it appears that the increase in agonist binding to nAChR occurs only after prolonged inactivation of the receptor.¹⁶ In contrast, a recent study demonstrated that increased high-affinity nicotine binding was paralleled by a twofold increase in acetylcholine-evoked currents that were less sensitive to desensitization. The differential reports relating function to increased binding may be due to different subunit combinations that all demonstrate increased agonist binding but differ in the effects on function. In keeping, Lindstrom and colleagues¹⁷ recently demonstrated that doses of nicotine that activate $\alpha_3\beta_2$ block the channel, whereas the nicotine dose that maximally activates the $\alpha_4\beta_2$ combination does not block the channel. Increased nicotinic agonist binding is not associated with changes in β_2 -nAChR mRNA,^{10,18,19} and the role of protein synthesis is not clear (e.g., no effect).^{20,21} There is increasing evidence that the upregulation results from a combination of increased receptor expression on the cell surface²² and decreased receptor turnover,^{10,23} and that this change is associated with persistent functional inactivation that occurs via distinct post-translational mechanisms and at rates and magnitudes that are nAChR-subtype specific.¹² Moreover, the magnitude of the effect of nicotine to upregulate nAChR agonist binding sites may be genetically determined. Feng and colleagues,^{24,25} who studied the gene expression of α_4 and β_2 subunits in 901 male siblings from 222 families, noted a strong association between the severity of nicotine dependence and haplotypes of the α_4 and β_2 subunits in men. While more studies are needed, these preliminary findings suggest that the propensity to develop nicotine dependence may be genetically determined, which may explain why some smokers are able to smoke "casually" while others develop severe dependence.

Another important question relates to how long the receptor upregulation lasts. In rodents, [³H]nicotine binding is elevated in brain for up to 3 days, and normalizes to baseline values within 7 days of nicotine withdrawal,²⁶ whereas in living human tobacco smokers abstinent for 4 to 9 days, nAChR measured using [¹²³I]5-IA-85380 are elevated compared to age-matched never smokers suggesting that the receptor has not yet normalized at 1 week of abstinence.²⁷ In post-mortem human brain, high-affinity nicotine binding in ex-smokers (>2 months) is similar to that of the nonsmokers, suggesting that the receptor normalized within a 2-month period of time.⁴⁻⁶ In a preliminary sample of living human smokers, this time frame is similar.²⁸ Thus, while the time period necessary for normalization is still unclear, it is apparent that the time frame for normalization in humans is longer than that noted in rodents.

An important consideration for measuring the nicotine binding site on nAChR in living humans is the time interval since the last cigarette required for residual nicotine to clear from brain so that it does not interfere with binding of the radioligand. Studies in nonhuman primates indicated that approximately 7 days would be required for nicotine to clear.²⁹ Thus, measurements of nAChR levels in humans should be obtained within a time interval in which the upregulation is still evident,

but yet, sufficient time for nicotine to clear has been achieved. An important note is that plasma nicotine levels, which have a half-life of approximately 2 h, are a poor indicator of clearance of nicotine or pharmacologically active metabolites from brain. In our studies of both nonhuman primates chronically administered nicotine and human tobacco smokers, we have found urine cotinine levels to be a reliable predictor of nicotine clearance from brain.

6.3.2 Dopaminergic Adaptations in Smokers

Alterations in dopamine (DA) levels are associated with the rewarding effects of abused substances including cigarettes. Specifically, the mesolimbic DA pathway, which originates in the ventral tegmental area (VTA) and projects to nucleus accumbens, is believed to be the primary reward pathway in brain.³⁰ nAChRs containing the $\alpha 7$ subunit ($\alpha 7$ -nAChR) are abundant in the VTA. Stimulation of these receptors by nicotine or by endogenous acetylcholine, whose release was induced by nicotine or other components of cigarette smoke, produces an increase in glutamate concentrations which in turn stimulate *N*-methyl-D-aspartate receptors (NMDARs) on DA-containing neurons in the VTA, facilitating DA release and enhancing dopaminergic function in this critical brain reward area.³¹ $\alpha 7$ -nAChRs are localized on glutamatergic terminals along with $\beta 2$ -nAChRs on gamma-aminobutyric acid (GABA) nerve terminals postsynaptic to DA neurons within the VTA. Additionally, $\beta 2$ -nAChRs are localized to DA cell bodies within the VTA. Nicotine actions on each of these strategically localized nAChRs are likely responsible for the interactions of nicotine with the DA reward pathway that mediates the development and maintenance of habitual tobacco smoking.³²

In human tobacco smokers, synaptic DA levels increase in response to smoking a single cigarette.³³ [¹¹C]raclopride binding to DA D₂ receptors is sensitive to endogenous DA levels and, thus, DA release may be determined by measuring the change in [¹¹C]raclopride binding to D₂ receptors after smoking a cigarette. After smoking a cigarette, [¹¹C]raclopride binding was reduced by 25.9 to 36.6% compared to the 0 to 13.6% decrease observed in smokers who did not smoke a cigarette, demonstrating that smoking a cigarette causes significant DA release in the striatal reward areas. Moreover, DA levels positively correlated with craving in left ventral caudate/nucleus accumbens ($r = 0.49$, $p = 0.04$) and in putamen ($r = 0.65$, $p = 0.004$) suggesting that the larger DA release provided a greater relief from craving. In a similar study design in nonhuman primates, nicotine caused a 5 to 6% reduction in [¹¹C]raclopride binding to D₂ receptors after a nicotine infusion in nonhuman primates.³⁴ The lower amount of DA release from nicotine challenge compared to a smoking challenge is not surprising and suggests that other chemical(s) in tobacco smoke may be contributing to the reinforcing properties of smoking by enhancing nicotine-induced DA release. Fowler and colleagues³⁵ have elegantly demonstrated that monoamine oxidase B (MAO-B, the primary catabolic enzyme for DA in the brain) is lower throughout the brain of living smokers (basal ganglia, thalamus, cerebellum, cingulate gyrus, and frontal cortex). Similar decreases have been noted in post-mortem brain of tobacco smokers where lower [³H]azabemide binding to MAO-B in amygdala was observed.³⁶ Because nicotine does not inhibit MAO-B,³⁷ it appears that the lower MAO-B levels in smoker's brain is due to chronic inhibition by other components of tobacco smoke. For example, tobacco smoke contains harmala alkaloids, including harmone and norharmone, that are potent monoamine oxidase inhibitors (MAOIs),³⁸ and Villegier³⁹ observed behavioral sensitization induced by repeated injections of nicotine in rats is short-lasting, but was prolonged upon the co-injection of a MAOI. These findings imply that behavioral effects of nicotine are transient and insufficient to induce long-term behavioral sensitization in the absence of MAOIs, suggesting that MAOIs contribute to the addictive properties of tobacco smoking. Collectively, these studies lead to the conclusion that the rewarding properties of tobacco smoking are mediated by the combined effects of nicotine and harmala alkaloids on DA release.

In addition to the acute effects of tobacco smoking on dopaminergic function in the striatal reward areas, there is significant evidence suggesting that the smoker's brain is in a chronic

hyperdopaminergic state. Uptake of L-dopa (the precursor to DA) is higher in smokers vs. non-smokers, suggesting DA biosynthesis is accelerated in smokers. In keeping, the striatal homovanillic acid (HVA)/DA ratio is lower in post-mortem brain of smokers compared to nonsmokers due to higher DA levels (as opposed to lower HVA).⁶ It is interesting to note that tyrosine hydroxylase (TH), the rate-limiting enzyme for DA biosynthesis, has been associated with vulnerability to develop nicotine dependence. Specifically, smokers that have the K4 allele of the TH enzyme are about 85% less likely to smoke in a dependent manner.⁴⁰ On the other hand, those carrying the K1 allele or three single nucleotide polymorphisms (SNPs) at the TH locus were not protected from developing nicotine dependence upon smoking. While the relationship of the K4 allele to TH expression and function is unclear, one may speculate that individuals with the K4 allele may synthesize DA at a slower rate, resulting in a smaller increase in DA in response to smoking and in turn decreasing reward salience and vulnerability to developing nicotine dependence.

The DA transporter has been suggested to be a critical dopaminergic substrate for habitual tobacco smoking because of its innate function — to regulate intrasynaptic DA availability and dopaminergic neurotransmission — and also because it has been genetically linked to nicotine dependence and age of smoking onset.⁴¹ However, studies of DA transporter availability in post-mortem human brain from elderly tobacco smokers⁶ and also in a younger population of living smokers did not detect a significant difference in striatal DA transporter availability. Moreover, there appears to be no significant relationship between DA transporter availability and smoking behavior.⁴² Interestingly, the vesicular monoamine transporter (VMAT₂), an intraneuronal carrier among all monoaminergic systems, is decreased in platelets of habitual smokers vs. nonsmokers.⁴³

With regards to DA receptors, postsynaptic DA D₁ receptors are decreased in living smokers as evidenced by lower [¹¹C]SCH 23390 binding in smokers compared to nonsmokers in the striatum, and most specifically in the nucleus accumbens.⁴⁴ Since [¹¹C]SCH 23390 binding to striatal D₁ receptors is insensitive to acute changes in extracellular DA concentration *in vivo*, it is likely that the decrease truly reflects altered D₁ receptor availability in smokers. Of note, the only study that has assessed D₁ receptors in post-mortem human brain of smokers compared to nonsmokers did not note any differences in D₁ receptor number.⁶ The discrepancy between the post-mortem and *in vivo* study in living smokers may be due to age differences in the subject populations studied, or may reflect confounds associated with studies in post-mortem tissue including length of storage time and post-mortem interval. Lower D_{1-like} receptor availability as observed in living smokers is a logical compensatory adaptive response to prolonged repeated perturbations in elevated synaptic DA levels. Alternatively, lower D_{1-like} receptor availability may be genetically determined. Currently, there is no evidence for a genetic relationship between the D₁ receptor genotype and smoking behaviors; however, preliminary evidence suggests that the T allele of the closely related D₅ receptor is protective against smoking initiation.⁴⁵ Because there are no drugs available that pharmacologically distinguish between D₁ and D₅ receptors, the relationship between D_{1/5} genotypes and receptor availability is unclear. However, it may be hypothesized that smokers smoke in effort to enhance dopaminergic signaling of an innately lower dopaminergic state that would make them more vulnerable to developing an addiction to tobacco smoking.

D₂ receptor function also appears to be aberrant in smokers as demonstrated by reduced growth hormone response to apomorphine challenge compared with nonsmokers. Interestingly, there was no difference between response to apomorphine during *ad libitum* smoking and 12 h of abstinence. These findings suggest that regardless of whether or not nicotine is on board, D₂ receptor sensitivity to DA agonists is reduced in smokers.⁴⁶ Importantly, D₂ receptor sensitivity to apomorphine was inversely correlated with cotinine serum levels and severity of nicotine dependence as measured by the Fagerstrom Tolerance Nicotine Dependence questionnaire (FTND). Reduced sensitivity of D₂ receptors to agonist stimulation likely reflects uncoupling of G proteins from the D₂ receptors, which would decrease the sensitivity to agonist stimulation but would not demonstrate a difference in D₂ receptor numbers measured using a radiolabeled antagonist.⁶ Further support for the D₂ receptor as a neurochemical substrate of smoking is provided by evidence demonstrating that

smokers carrying the A1 allele of the D₂ receptor have reduced P300 amplitude compared to nonsmokers⁴⁷ and carriers of the rare B1 allele for the D₂ receptor gene are more likely to be ever smokers.⁴⁸ In addition, the D₄ VNTR polymorphism moderates reactivity to smoking cues. Specifically, carriers of the DRD₄ L polymorphism demonstrate greater craving, attention, and arousal in response to smoking cues.⁴⁹ In contrast, individuals carrying the D₄ S allele do not demonstrate reactivity to smoking cues. Collectively, these studies support the D₂-like receptors as critical substrate for vulnerability to tobacco smoking.

6.3.3 GABAergic Adaptations in Smokers

GABA is a major neurotransmitter in the mammalian brain and controls neuronal excitability. It has been implicated in the addictive and withdrawal processes of nicotine dependence. Nicotine stimulates GABA release via modulation of nAChR on GABAergic neurons, which could lead to a decrease in inhibitory tone from GABAergic stimulation of GABA_B autoreceptors.⁵⁰ Alternatively, nicotine-induced alterations in the levels of neurosteroids that regulate GABA_A receptors could also potentially lead to altered levels of GABA.⁵¹ Changes in GABA might also occur through nicotine's actions at the nAChR, which increases GABA release. Nicotine-induced GABA release is blocked by mecamylamine and dihydro- β -erythroidine and the effect is lost in the β_2 knockout mice, suggesting that β_2 -nAChR mediate GABA release. The α_7 nAChR antagonist, alpha bungarotoxin, did not alter release.^{52,53} Nicotine-induced GABA release has been demonstrated in the thalamus, hippocampus, and throughout the cerebral cortex.^{54–60} The differential effects of nicotine on GABA release may be due to regional differences in nAChR subunit combinations in different regions.

Cortical GABA is also dysregulated in disorders associated with affective instability,⁶¹ including premenstrual dysphoric disorder. Since nicotine modulates GABA function, Epperson and colleagues⁶² suggest it is possible that nicotine modulates mood.⁶² In a magnetic resonance spectroscopy (MRS) study of men and women smokers abstinent for 48 h, cortical GABA levels were decreased in women smokers imaged during the follicular phase (when hormone levels are similar to those in men) as compared to men. Furthermore, there were no differences in GABA levels between men smokers and nonsmokers but there was a drastic decrease in GABA levels in women smokers compared to women nonsmokers during the follicular phase of the menstrual cycle. These findings suggested that the phasic differences in cortical GABA levels evident in women nonsmokers are suppressed in women smokers. Since menstrual cycle phase was confirmed by serum estradiol and progesterone levels, changes in GABA levels cannot be attributed to lack of hormonal cyclicality.

The acute or chronic regulatory effects of nicotine treatment or tobacco smoking on cortical GABA_A-benzodiazepine receptors (GABA_A-BZR) are poorly studied. To date, only one animal study has examined effects of chronic nicotine and has demonstrated increased GABA_A-BZ receptors.⁶³ In addition to nicotine, tobacco smoke also contains the β -carboline harman and norharman,⁶⁴ which are well known as MAOIs,^{65,66} but may also be inverse agonists at the GABA_A-BZ receptor.⁶⁷ Currently, it is not clear what the combined effects of nicotine and β -carbolines are on GABA_A-BZR.

There is some evidence for a role for GABA_B receptors as a neurochemical substrate of tobacco smoking. GABA_{B1} receptors appear to be regulated by nicotine. Li⁵⁰ demonstrated a significant reduction of GABA_B receptor mRNA in the hippocampus in rats chronically treated with nicotine. GABA_B receptors primarily function to modulate release of neurotransmitters including GABA, glutamate, acetylcholine, noradrenalin, and serotonin that in the hippocampus are important for cognitive processes including attention and memory. Thus, nicotine-induced alterations in GABA_B receptor expression in the hippocampus, a widely accepted site for learning and memory in both humans and animals, may be implicated in cognitive properties of tobacco smoke on cognition. A genetic linkage between GABA_{B2} and nicotine dependence has been demonstrated in African American and European Americans.⁶⁸

6.3.4 Opioidergic Adaptations in Smokers

The endogenous opioid system is believed to be the primary common pathway for all drugs of abuse. However, the role of the opioid system in habitual tobacco smoking has only recently become of interest. Using the short-acting mu-opioid antagonist naloxone, some studies have found decreases in smoking behavior in short-term laboratory paradigms^{69,70} while others have reported no effect of naloxone on smoking behavior.⁷¹ The long-acting mu-opioid antagonist naltrexone has been studied more extensively and has been shown to reduce smoking behavior and craving for cigarettes.^{72,73} When used in combination with the nicotine patch, naltrexone has been shown to reduce smoking behavior and tobacco craving⁷⁴ and craving in response to cues,⁷⁵ as well as to block some effects of nicotine.⁷⁶ Evidence from clinical trials of naltrexone is equivocal with both positive^{74,77} and negative findings.^{78,79} Preclinical evidence suggests that the effects of naltrexone on cigarette smoking may be mediated by its ability to differentially alter expression and function of the α_7 and $\alpha_4\beta_2$ nAChRs in the central nervous system.⁸⁰

Nicotine administration causes release of the endogenous opioid peptide beta-endorphin.⁸¹ Preclinical evidence suggests that the mu opioid receptors are involved in nicotine reward.⁸² Nicotine induced sufficient beta-endorphin to displace binding of the mu opioid receptor agonist [¹¹C]-carfentanil in brain in recently abstinent male smokers. Importantly, Scott and colleagues⁸³ used [¹¹C]carfentanil and positron emission tomography (PET) to demonstrate that nicotine, but not denicotinized cigarettes, induced endogenous opioid release in the thalamus and amygdala but reduced release in the anterior cingulate suggesting that nicotine was the sole chemical in tobacco smoke responsible for activation of the opioid reward pathway in the thalamus, amygdala, and cingulate. This suggests opioid changes in the cingulate mediate craving for nicotine while the opioidergic changes in the thalamus and amygdala may mediate the feelings of “satisfaction” after smoking a cigarette.

Lerman and colleagues⁸⁴ proposed that OPRM1 (mu-opioid receptor gene) may be responsible for efficacy of the type of nicotine replacement therapy and examined the relationship of the OPRM1 in relation to response to different nicotine replacement therapies. Smokers carrying the less common OPRM1 Asp40 variant were significantly more likely than those homozygous for the wild-type Asn40 variant to be abstinent at the end of nicotine replacement phase, with the effect being significant for the transdermal nicotine vs. nicotine nasal spray therapies. Furthermore, individuals with Asp40 variant treated by transdermal nicotine exhibited a significantly higher rate of recovery from short smoking lapses than those with Asn40 variant and significantly less negative side effects of smoking cessation (e.g., weight gain and withdrawal symptoms). These findings suggest that nicotine replacement therapies will be more efficacious in carriers of the Asp40 variant for the opioid receptor.

6.3.5 Serotonergic Adaptations in Smokers

Serotonin (5-HT) regulates many bodily functions, including appetite⁸⁵ and sleep (i.e., modulation of REM latency)⁸⁶ and may be involved in initiation and maintenance of tobacco smoking. Drugs that enhance 5-HT levels facilitate smoking cessation in highly dependent smokers.^{87–89} In turn, nicotine has been shown to elevate 5-HT levels by stimulating 5-HT release through binding to the nAChR⁹⁰ and inhibiting 5-HT reuptake.^{90,91} 5-HT levels are further enhanced in the smoker's brain as a consequence of decreased monoamine oxidase-A (MAO-A; the neuronal enzyme which serves to degrade 5-HT) activity.³⁵ Similar decreases in MAO activity have been noted in platelets of smokers⁹² and support reports of twofold higher platelet 5-HT levels in smokers as compared to nonsmokers.⁹³ In addition, nicotine has been shown to decrease platelet 5-HT release and inhibit 5-HT uptake.⁹⁴ Active smokers excrete approximately 30% more 5-HT and 5-hydroxyindoleacetic acid (5-HIAA) as compared to never smokers and former smokers.⁹⁵ In the central nervous system, nicotine and its primary metabolite cotinine both decrease 5-HT turnover in rat brain, which results

in a net enhancement in 5-HT neurotransmission. The 5-HT transporter (5HTT) regulates magnitude and duration of serotonergic neurotransmission. Chronic exposure to nicotine is associated with reduction in 5HTT sites in the brain⁹⁶ and nicotine dependence (as assessed using FTND questionnaire) has been found to be inversely correlated with densities of platelet 5HTT.^{97,98} In brain, diencephalon 5-HT transporter availability is not altered in living human tobacco smokers.⁴² However, there is a trend for higher brain stem 5-HT transporter availability in smokers vs. nonsmokers (10% higher in smokers), which appears to be more evident in men than women smokers. The perturbations in 5-HT function induced by nicotine may in part contribute to the reinforcing properties of cigarette smoking. In keeping, smoking cessation is facilitated by enhancing 5-HT function by administration of the MAO-A inhibitor moclobemide in highly dependent smokers.⁹⁹

5-HT_{1A} receptor gene expression is higher in DG, C1, and C3 subfields of the hippocampus after 2 and 24 h nicotine administration in rodents,¹⁰⁰ suggesting that nicotine is capable of modulating 5-HT_{1A} receptor expression in some cortical and limbic brain regions. Rasmussen and Szachura¹⁰¹ examined the effects of 5-HT_{1A} agonist 8-OH-DPAT on the single-unit activity of serotonergic neurons in anesthetized rats undergoing nicotine withdrawal. They demonstrated a significant increase in the DRN to the 5-HT_{1A} agonist 8-OH-DPAT during nicotine withdrawal, which led to an enhanced startle response. They report an increase in sensitivity develops over time with significance at days 3 and 4, and dropping to baseline by day 7. This finding may suggest that pre- and post-synaptic 5-HT_{1A} antagonist drugs may be useful in attenuating some of the symptoms of nicotine withdrawal, therefore contributing to smoking cessation in humans. 5-HT_{2A} receptors play a role in schizophrenia and alcohol dependence, both of which are associated with high prevalence of smoking behavior. However, the specific role of this receptor in smoking has not been widely studied. One study showed an association between 5-HT_{2A} and maintenance of smoking but not smoking initiation.¹⁰²

6.3.6 Implications for Smoking Cessation Treatments

Tobacco smoking is currently the most prevalent and deadly addiction. While there are numerous treatments currently available, there is a lot of room for improvement. Two types of pharmacological therapies have been approved by the U.S. Food and Drug Administration (FDA) — nicotine replacement therapies including gum, transdermal patch, lozenge, and inhaler, which deliver nicotine without the tar, and non-nicotine-based therapy such as bupropion hydrochloride (Zyban). There is significant between-subject variability in the efficacy of nicotine and non-nicotine-based pharmacotherapies, which could play a role in individual ability to quit and abstain from tobacco smoking. Factors such as genetic susceptibility, including family history, are currently being investigated in an effort to enhance the effectiveness of pharmacotherapies for smoking cessation. Because of the critical roles in drug reward, DA and opioid substrates are candidates for smoking cessation pharmacotherapies. Stimulation of D₂ receptors via bromocriptine decreases smoking, whereas D₂ receptor antagonism via haloperidol facilitates smoking. Zyban (bupropion), an atypical anti-depressant, has demonstrated efficacy for promoting long-term abstinence by reducing nicotine-related withdrawal symptoms,¹⁰³ negative affect,¹⁰⁴ and craving.¹⁰⁵ Zyban's mechanism of action for reducing smoking is believed to be inhibition of DA and norepinephrine reuptake, enhancement of norepinephrine and 5-HT neuronal activity, as well as noncompetitive inhibition of $\alpha_3\beta_2$, $\alpha_4\beta_2$, and α_7 nAChRs. However, Zyban is not equally effective in all smokers. For example, David and colleagues¹⁰⁶ demonstrated that individuals with *DRD2-Taq1* A2/A3 experience less craving upon smoking cessation, and reduced anxiety and impatience as compared to those with *DRD2-Taq1* A1/A2 or A1/A1 who demonstrated no reduction in withdrawal symptoms.

Several other clinically available pharmacological agents have been tested for their potential to facilitate smoking cessation, although they are not approved by the FDA for this purpose. For example, tricyclic antidepressants, which inhibit reuptake of noradrenaline and 5-HT, promote smoking cessation in conjunction with behavioral treatment in some individuals.¹⁰⁷ However, these

medications are limited because of their significant side effects. 5-HT-selective reuptake inhibitors (SSRIs) are believed to be a safer class of antidepressants but have not demonstrated effectiveness in smoking cessation.¹⁰⁸

Cohen proposed that there may be a third way to treat nicotine dependence.¹⁰⁹ Since smokers still experience withdrawal symptoms with bupropion, and nicotine replacement therapies are not fully effective, Cohen and colleagues examined the effect of using a nicotinic receptor agonist in order to aid in smoking cessation. A novel nAChR ligand SSR591813 was employed due to its selective $\alpha_4\beta_2$ partial agonist activity. SSR591813 reduced the number of nicotine infusions on day 2 and 3 of treatment. Unlike mecamylamine, SSR591813 did not precipitate withdrawal signs in nicotine-exposed rats but prevented withdrawal signs precipitated by mecamylamine. Cohen and colleagues suggest these results imply $\alpha_4\beta_2$ involvement in the nicotine withdrawal syndrome. Since the SSR591813 may moderate nicotine withdrawal symptoms, which have been shown to cause enough distress to individuals that they relapse, it is important to continue investigation in its use for smoking cessation.

6.4 NEUROCHEMICAL AND NEUROBEHAVIORAL CONSEQUENCES OF METHAMPHETAMINE ABUSE

Colin N. Haile, Ph.D.

Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut and VA Connecticut Healthcare System, West Haven, Connecticut

Methamphetamine (METH) is a highly addictive and potent central nervous system (CNS) stimulant. Its rapid and escalating abuse in the U.S. has highlighted deficiencies in our understanding of the neurobiological mechanisms that underlie its powerful reinforcing effects. Availability of the drug facilitated through technological advances in synthesis and drug trafficking from other countries has also contributed to its rapid dissemination. According to the National Survey on Drug Use and Health, 12.3 million Americans have tried METH at least once, an increase of 40% from 2000 and 156% over 1996 numbers.¹ Although METH abuse was originally concentrated in the western part of the U.S. (Hawaii, California) recent statistics indicate a dramatic shift in its use to rural Midwest States. The National Clandestine Laboratory Database notes that the number of small-scale labs producing METH increased substantially in the Midwest (Illinois, Michigan, Ohio, Pennsylvania)² indicative of the redistribution of METH production and abuse in the U.S.³ Availability of the drug, in turn, has resulted in substantial increases in substance abuse treatment admissions. Moreover, METH use is often associated with high-risk behaviors for transmitting HIV and other diseases. Because METH abuse has a profound impact on the health of the individual and society at large it is paramount that we gain a better understanding of its effects on the human brain and its medical consequences.

6.4.1 Military, Medical Use, and Eventual Abuse of METH

METH is a derivative of amphetamine (AMPH) and both have many similarities in their effects on brain chemistry and behavior. They also share a common use history. AMPH was originally synthesized by Lazar Edeleanu in 1887 and again independently synthesized in 1927 by Gordon Alles.⁴ It was eventually introduced commercially for the treatment of a myriad of ailments ranging from schizophrenia to hiccups.⁵ AMPH has been used by the military to enhance concentration and vigilance ever since the Spanish Civil War. In World War II, American, German, British, and Japanese fighter pilots were administered the drug to stave off fatigue on long missions, a common use even today.⁶ First synthesized by the Japanese pharmacologist Nagayoshi Nagai in the late 1800s, METH was also used during World War II to reduce soldier fatigue during military action and by civilians working in factories supporting the war effort. Similar to AMPH, METH was eventually sold over the counter in Japan beginning in 1941 as *Philopon* and *Sedrin*. Following the end of World War II, availability of METH increased further due to army surplus flooding the market. This initiated what has been called the “First Epidemic” (1945–1957) of METH abuse in Japan. Soon over half a million individuals were heavily abusing the drug, including 5% of the population between the ages of 16 and 25.⁷ Strict laws were implemented in the 1950s to help deal with the problem. A “Second Epidemic” occurred in the 1970s when METH use increased among blue-collar workers, students, and housewives.⁸ At present, METH abuse continues to be a serious

problem in Japan and has remained the most popular illicit drug for the last 10 years.⁹ In the U.S., underground METH labs appeared in California Bay Area in the 1960s. Recognizing the profitability of METH, motorcycle gangs began distributing the drug along the West Coast. METH abuse was so rampant it was the topic of a popular book at the time.¹⁰ Drug enforcement crackdowns on gang activity and limitation of precursor chemicals for the synthesis of METH quelled the distribution to a certain degree. At present, however, the bulk of the West Coast drug supply — and the Midwest — appears to be coming from Mexican “super labs” with a minor percentage produced by small-scale establishments or so called “mom-and-pop” laboratories.³

6.4.2 Characteristics and Patterns of Use and Abuse

METH has been available legally in the U.S. for many years as a therapeutic drug (trade name Desoxyn) used to treat obesity and attention-deficit/hyperactivity disorder (ADHD). Illegal street forms are commonly known as “speed” or “meth,” which can be self-administered via injection, smoking, nasal inhalation (“snorting”), or oral ingestion. In its highly pure smokable form it is referred to as “crystal,” “ice,” “crank,” or “glass.” When ingested, the lipophilic compound efficiently penetrates the CNS,¹¹ increasing concentrations of monoamines (particularly dopamine, DA) through multiple mechanisms (see below).¹² The intensity of the “high” and mood alteration produced from METH ingestion is route dependent. Smoking and injection results in an almost immediate euphoria or “rush,” whereas the effect is less intense and rapid when administered via “snorting” (effects felt within 3 to 5 min) or oral ingestion (15 to 20 min).¹ The half-life of METH is an impressive 10 h in humans (compared to 90 min for cocaine).^{13–15} METH abusers tend to self-administer the drug in a “binge and crash” pattern. “Binges” or “Runs” may last for 1 to 3 days or more followed by a period of abstinence. Because of the long half-life of METH in humans, “binge” administration results in successive accumulation of residual drug in the system. Tolerance to many — but not all — of the peripheral and central effects of METH occurs almost immediately.^{16,17} Acute METH intoxication results in powerful stimulation of the sympathetic nervous system resulting in mydriasis (pupil dilation), hypertension, tachycardia, diaphoresis, and hyperthermia. The reinforcing or positive effects of acute administration include euphoria, increased energy, heightened attentiveness, hypersexuality, and decreased anxiety.^{18,19} Upon withdrawal from METH the individual is said to “crash,” which is discernible by the presence of depression, anhedonia, irritability, anxiety, fatigue, hypersomnia, poor concentration, intense craving, and aggression.^{19–22} In certain respects, symptoms are more intense and distinguishable from amphetamine and cocaine withdrawal.^{21,23,24} Individuals who have been consuming METH frequently and for long periods of time show severe psychiatric disturbances or METH “psychosis,” which has many characteristics in common with schizophrenia.^{9,25–28}

6.4.3 Neurochemistry of METH: Mechanisms of Action and Reinforcement

6.4.3.1 Dopamine

METH is similar to other drugs of abuse in that its reinforcing effects are mediated through multiple sites and mechanisms in the brain. It is well established that drugs of abuse — and natural reinforcers such as food — exert their effects, in part, by activation of the mesolimbic DA system.^{29–31} This system consists of DA cell bodies in the ventral tegmental area (VTA) and their forebrain terminals in the prefrontal cortex (PFC) and nucleus accumbens (NAC). Drugs abused by humans evoke DA release in the PFC and NAC, the latter a crucial brain substrate that mediates the reinforcing or addictive aspects of drugs of abuse.³² It is hypothesized that DA release in these areas increases the saliency or attractiveness of rewarding stimuli contributing to the addiction process.³³ Addictive drugs including METH are self-administered under controlled conditions^{34,35} and activate mesolimbic DA in humans.³⁶ Lesions at different loci of this system alter the behavioral

effects of drugs of abuse in animals.^{37,38} Released DA from terminal regions subsequently binds to a number of DA receptor subtypes such as D₁-like (D₁, D₅) or D₂-like (D₂, D₃, D₄), which are classified based on molecular and pharmacological characteristics. DA neurotransmission is then terminated by sequestration of the transmitter into the presynaptic neuron through the dopamine transporter (DAT).^{39,40} Depending on the behavioral paradigm, drugs that block DA receptors alter the behavioral effects of drugs of abuse to varying degrees.³⁰

In animals, repeated intermittent psychostimulant administration (i.e., cocaine, AMPH, METH) enhances locomotor behavior over time. This phenomenon is referred to as behavioral sensitization. Sensitization is considered a key characteristic in the development of drug addiction and believed by some to be a model of psychosis or schizophrenia.^{41–43} Induction of sensitization appears to be related to enhancement of DA neurotransmission in the mesolimbic DA system although other neurotransmitters such as glutamate (GLU), serotonin (5-HT), and norepinephrine (NE) are involved.⁴⁴ Drugs that block behavioral sensitization may have pharmacotherapeutic potential. Another important concept in addiction is tolerance. Tolerance is the decrease in behavioral response to the same dose of the drug over time and most likely plays a role in the increasing amounts of ingested drug over time by drug addicts.⁴⁵

Similar to cocaine and AMPH, METH has strong effects at the DAT, which are likely responsible for its potent addictive properties. In fact, cocaine's reinforcing effects are related to its ability to enhance extraneuronal DA concentrations by blocking the DAT.⁴⁶ Likewise, AMPH increases DA levels by primarily reversing the DAT and inducing transmitter release into the extracellular space.^{47,48} Strong evidence supporting this assumption comes from finding that neither cocaine nor AMPH is effective in genetically modified mice lacking this transporter.⁴⁹ Acute administration of METH also potently increases DA concentrations in reward circuitry^{50–52} via an exchange diffusion mechanism independent of neuronal depolarization⁵³ and by redistributing cytosolic DA to areas in the neuron for quick fusion and discharge.^{54,55} Systemic treatment for 7 days with METH enhances the response of mesolimbic VTA cell body neurons to subsequent administrations of the drug. This effect is antagonized with Ca²⁺channel blockers.⁵⁶ A similar treatment regimen (5 days) results in hypersensitivity of VTA neurons altering the maximum amplitude and the ED₅₀ value of D₂ receptor mediated hyperpolarization.⁵⁷ Hyperpolarization (i.e., inhibition) of DA neurons in the VTA may be a compensatory mechanism engaged to decrease excessive DA release in the NAC. However, an attenuation of DA release in this terminal region results in sensitized DA receptors, which is perhaps also compensatory. Consistent with this notion, *in vitro* intracellular recording in brain slices from rats pretreated with METH show supersensitized D₁ receptor-mediated hyperpolarizations in the NAC.⁵⁸

The exact mechanisms responsible for the ability of METH to increase extracellular DA are fairly well delineated and are, in part, due to facilitation of DA discharge and inactivation of the DAT. For instance, the release of massive quantities of DA facilitates the formation of reactive oxygen species via auto-oxidation of DA⁵⁹ that, in turn, inactivates DAT.^{60,61} Inactivation of DAT increases synaptic DA by preventing reuptake into the presynaptic neuron. Other reactive species such as superoxide or peroxynitrite also inactivate DA by oxidization, transforming it into highly reactive DA quinones that can also compromise DAT function.^{62,63} Indeed, experiments show that acute and chronic administrations of METH cause a rapid and reversible decrease in the DAT.^{64,65} Remarkably, a single METH injection dose-dependently decreases [³H]dopamine uptake into striatal synaptosomes 1 h after treatment, suggesting rapid deleterious effects on DAT function.⁶⁴ DAT inactivation is blocked by depleting DA using the tyrosine hydroxylase inhibitor α -methyl-*p*-tyrosine⁶⁶ and by pretreatment with D₁ and D₂ antagonists and DAT blockers.^{66–68} This suggests that abnormally high levels of DA evoked by METH may be the causative agent underlying DAT inactivation. Yet, studies also demonstrate that the potent hyperthermic effects of METH aid in enhanced production of reactive oxygen species that may further contribute to the inactivation of DAT.^{63,69} Neutralizing METH-induced increases in body temperature⁶⁶ blocks its effects on the DAT, suggesting that inactivation involves a multicomponent process.

As DA is taken back up into the presynaptic neuron, it is sequestered into synaptic vesicles and repackaged for storage and subsequent re-release, a process mediated by the vesicular monoamine transporter (VMAT-2) in monoaminergic neurons. Once inside the neuron, DA is protected against oxidation, which could produce reactive oxygen species implicated in DAT inactivation.⁷⁰ Indeed, acute and multiple administrations of METH rapidly and persistently (up to 24 h) alter (within 60 min) vesicular [³H]DA uptake as assessed in vesicles purified from striatum.^{71,72} Pretreatment with the DA D₂ antagonist eticlopride but not the D₁ antagonist (SCH23390) prevents decreases in vesicular DA uptake by METH.⁷³ These data implicate D₂ receptors in METH-induced decreases of VMAT-2. As mentioned previously and consistent with other transmitter releasing compounds,⁴⁷ METH administration redistributes vesicles within the nerve terminal for immediate release, interestingly, in a fashion opposite to that of cocaine.⁷⁴ The distinctive difference between the two drugs may contribute to differences in their neurotoxic and behavioral profiles. Subcellular fraction preparations from striatum in rats analyzed at 24 h after METH administration show reduced overall VMAT-2 protein suggesting actual degradation occurs.⁷⁵ Taken together, VMAT-2 inactivation would hypothetically lead to increased cytosolic DA levels and potential formation of reactive oxygen species by auto-oxidation or by monoamine oxidase (MAO) leading to neurotoxicity,⁷⁶ a prominent feature of chronic METH consumption.⁷⁷

6.4.3.2 Serotonin

In a number of ways, the effects of METH on serotonin (5-HT) are similar to those on DA. For example, repeated METH injections increase hippocampal (250%, over controls)⁷⁸ and nucleus accumbal (900%) extracellular 5-HT levels.⁵² Long-lasting deficits in 5-HT metabolite parameters occur in the striatum, hippocampus, and frontal cortex in response to multiple administrations of METH.^{79,80} A single high dose of METH (15 mg/kg) decreases tryptophan hydroxylase — the rate limiting enzyme in 5-HT synthesis — in the NAC and caudate.⁸¹ Previous studies confirm these effects and posit that — similar to DA — inactivation may be caused by reactive oxygen species formed inside 5-HT terminals oxidizing the enzyme and causing deleterious effects to the neuron.^{79,82,83} Acute and multiple injections of METH (10 mg/kg) result in reversible decreases in 5-HT transporter (SERT) function *in vivo*^{68,84} whereas high doses of fenfluramine, cocaine, or methylphenidate do not.⁸⁵ High (15 mg/kg) but not low (7.5 mg/kg) doses of METH administered repeatedly reduces the binding of [³H]cyanoimipramine ([³H]CN-IMI) to serotonin uptake sites assessed by quantitative autoradiography.⁸⁶ Similar to DA, studies have shown that inactivation of SERT may also be due to the production of reactive oxygen species such as the endotoxin tryptamine-4,5-dione, a by-product of oxidized 5-HT.⁸⁷ Acute METH administration blocks SERT function in the striatum but not in the hippocampus. This effect appears to be mediated through DAergic pathways and partly by the hyperthermic effects of METH. Decreasing METH-induced increases in body temperature, depleting striatal DA with α -methyl-*p*-tyrosine, or pretreatment with D₁ and D₂ antagonists (SCH23390 and eticlopride) blocks the ability of METH to decrease SERT activity in the striatum but not in the hippocampus.⁸⁸ These results suggest that the action of METH on SERT localized in the striatum is predominantly mediated through DA and that hyperthermia also plays a role. Hippocampal changes appear to be dependent on 5-HTergic pathways. In addition, like DAT blockers, SERT blockers (citalopram and chlorimipramine) are also neuroprotective.^{82,89}

6.4.3.3 Norepinephrine

Evidence from human and animal studies highlights a unique role for norepinephrine (NE) in the neurobiological effects of METH. For example, METH increases extracellular NE divergently in the caudate and hippocampus of rodents as measured by microdialysis.⁹⁰ Depletion of NE with the selective neurotoxin *N*-(2-chloroethyl)-*N*-ethyl-2-bromobenzylamine (DSP-4) (50 mg/kg) significantly enhances METH-induced striatal DA depletion in rodents.⁹¹ Pharmacological blockade

of NE with clonidine, a drug that shuts down NE release via presynaptic α_2 adrenergic autoreceptors, potentiates METH-induced effects, whereas blockade of α_2 with antagonists (e.g., yohimbine), which enhances release, reduces the drug's deleterious effects.⁹¹ These results suggest that NE may help attenuate alterations in neurochemistry attributed to DA. An early study also demonstrated that METH-induced increases in tryptophan hydroxylase activity are blocked with the NE antagonist propranolol indicating NE and 5-HT coordinate in some unknown way.⁹² Unlike DAT and SERT, however, NET appears to be less vulnerable to the adverse effects of METH. METH treatment does decrease NET activity in synaptosomes; however, these changes are due to a direct effect of the drug on the transporter and not by indirect inactivation via reactive oxygen species seen with DA and 5-HT. Indeed, the aberrant effects on NETs can be reversed by simply rinsing the *in vitro* preparation of residual METH.⁹³ In addition, high doses of METH administered over a 2-week period results in depletion of DA and 5-HT but not NE in nonhuman primate brain.⁹⁴ Similarly, single or repeated METH administration reduces many neurochemical metabolic parameters associated with DA and 5-HT but not NE in the striatum-accumbens and thalamus-hypothalamus in mice.⁹⁵ Although it appears that NE plays a minimal role in the action of METH on the brain, there is evidence NE may be important. An *in vitro* study has recently shown that oral doses of psychostimulants, including METH, which produce subjective effects in humans, correlate with their potency to release NE not DA or 5-HT,⁹⁶ and prazosin, an α_1 adrenergic antagonist, blocks cocaine-induced reinstatement in an animal model of relapse.⁹⁷ Moreover, human METH abusers who develop spontaneous recurrence of METH psychosis show markedly elevated NE plasma levels, indicating that this neurotransmitter may be of prime importance.⁹⁸

6.4.4 Neurobehavioral and Neuropharmacological Effects of METH: Pharmacotherapeutic Targets

Experiments in rodents and other animals allow us to closely examine the complex interplay between the drive or motivation to consume addictive drugs and behavior. This information has helped determine the neurobiological substrates that are responsible for the reinforcing or addictive effects of drugs of abuse.⁹⁹ Accumulating evidence suggests that the robust abnormal drug-seeking behavior seen in the addicted state is due, in part, to drug-induced alterations in neural sensitivity, neurotransmitter levels, and neural plasticity that is heavily embedded in learning.^{100,101} Teasing out the mechanisms behind drug-induced alterations in brain proteins in areas that mediate these addictive states is of prime importance. Likewise, drugs that reverse or block these changes may serve as useful pharmacotherapies. Therefore, the effects of METH in the context of motivation and drug-induced changes in reinforcement-related brain circuits and possible drug therapy targets are reviewed below.

6.4.4.1 Dopamine's Vital Contributions to METH-Induced Reinforcement

Similar to cocaine and AMPH, acute administration of METH (2 mg/kg) potently increases DA in the NAC 1000% over baseline levels.^{102,103} METH administration also leads to the development of behavioral sensitization^{95,104} that is heavily dependent on dose and drug regimen.^{105,106} As a testament to the reinforcing properties of METH, and like other psychostimulants, the drug is readily self-administered across a number of species.^{107–112} In fact, self-administration of METH in combination with other drugs of abuse such as heroin makes it even more reinforcing.¹¹³ Consistent with the action of METH on the DA system, drugs that modulate DA in one way or another alter METH-induced behaviors. For example, co-treatment with either a D_1 (SCH23390) or a D_2 (YM-09151-2) antagonist blocks the development and expression of METH-induced (4 mg/kg) behavioral sensitization in rats over 14 days of treatment.¹⁰⁴ Correspondingly, Witkin et al.^{104a} demonstrated that pretreatment with the highly selective D_1 antagonist SCH39166 or the D_2 antagonist spiperone blocks the behavioral activation of METH (0.3 mg/kg) in mice. METH-

induced behavioral sensitization in animals is used as a model of psychosis and drugs that antagonize this effect may be useful in treating disorders such as schizophrenia.⁴³ Particular attention has been focused on the D₄ receptor subtype when it was discovered that the atypical antipsychotic clozapine blocks this receptor among its many other actions.¹¹⁴ Pretreatment with a selective D₄ antagonist (NRA 0160) blocks METH-induced hyperactivity in mice to a similar degree to that of clozapine.¹¹⁵ It is unknown if clozapine would prove a useful treatment for METH abuse.

Given that METH, and other psychostimulants, readily bind and modulate SERT, DAT, and NET to varying degrees, compounds acting on these transporters in unison may prove therapeutic. Indatraline, a compound that binds to 5-HT, NET, and DAT, was recently shown to inhibit METH-induced DA release *in vitro*.¹¹⁶ In a rat model of relapse, priming injections of indatraline marginally reinstated previously extinguished cocaine-seeking behavior (lever pressing for drug) as measured by self-administration yet failed to alter overall drug intake.¹¹⁷ Along these lines, the 3-phenyltropane analogue RTI 111 that is marginally selective for the DAT, yet also has proclivity for the other transporters, increases the potency of self-administered METH in nonhuman primates.¹¹⁸ Although counterintuitive, other drugs that enhance the effects of psychostimulants such as cocaine to the point at which they are aversive have proven efficacious.¹¹⁹ However, RTI 111 is readily self-administered in a manner similar to cocaine and thus may possibly be abused itself. Other drugs that are more selective for the DAT, such as GBR12909, have been tested. GBR12909 inhibits AMPH transport into striatal synaptosomes suggesting that it could attenuate the behavioral effects of its cousin METH.¹²⁰ Similar to RTI 111, however, GBR 12909 co-treatment with METH potentiates the discriminative stimulus effects of METH in rats, a behavioral model that tests the subjective effects of drugs.¹²¹ Moreover, priming injections of GBR 12909 reinstated previously extinguished cocaine-seeking behavior as measured by self-administration.¹¹⁷ The results mentioned above emphasize the fact that experimental results attained *in vitro* are poor predictors for how the drug will behave *in vivo*. Nevertheless, a recent study with a long-lasting version of GBR12909 shows promise as a treatment for METH addiction in preclinical models.⁵² Whether compounds targeting the DAergic system will produce optimal treatments for METH remains to be seen.

6.4.4.2 Serotonin Modulation of the Reinforcing Effects of METH

Aside from the known contribution of DA, preclinical studies indicate 5-HT plays a role in the reinforcing effects of drugs of abuse. For instance, mice lacking 5-HT_{1B} receptors are hypersensitive to the behavioral activating effects of cocaine.¹²² Lesions of forebrain 5-HTergic tracts increase amphetamine self-administration suggesting that 5-HT regulates DA-mediated effects to a degree.¹²³ Indeed, it is well known that stimulating 5-HT by various means can augment DA neurotransmission.^{124,125} Although the contribution of 5-HT in the effects of METH is not fully known, METH does indeed potently activate the 5-HTergic system⁸⁴ enhancing release¹²⁶ and increasing extracellular levels in brain.⁹⁰ Munzar et al.¹²⁷ demonstrated that the powerful 5-HT-releaser fenfluramine initially decreases METH self-administration. However, due to unknown mechanisms, tolerance developed to this effect after repeated dosing.¹²⁷ Results from drug discrimination experiments in that same study found that various 5-HT compounds targeting a number of receptor subtypes modulate and/or generalize to the discriminative stimulus effects elicited by METH.¹²⁷ These results are consistent with other studies demonstrating the modulatory effects of 5HT on METH-induced behaviors. For example, pretreatment with 5-HT_{1A} (NAN-190), 5-HT_{1B/1D} (methiothepin), and 5-HT_{2C} (mianserin) antagonists attenuates the acute locomotor stimulating effects of METH, whereas 5-HT_{2A/2B} (methysergide) and 5-HT₃ (ondansetron) antagonists potentiate the METH effects.^{128,129} The mechanisms that underlie the ability of different 5-HTergic compounds to divergently alter the behavioral effects of METH are unknown. Taken together, however, these data suggest that 5-HT likely plays more of a modulatory role than that of DA in METH-induced behaviors.¹³⁰ Drugs acting on this system may prove useful treatments especially for abnormalities in mood and aggression associated with METH withdrawal.

6.4.4.3 Glutamate and METH-Induced Behaviors

Glutamate (GLU) is the most abundant neurotransmitter in the brain and clearly has an important position in addiction. Indeed, GLU is essential in psychostimulant-induced sensitization¹³¹ and reinforcement^{132,133} by possibly altering DA neurotransmission in the PFC.¹³⁴ Remarkably, mice genetically lacking the metabotropic GLU receptor GluR5 are immune to the locomotor and reinforcing effects of cocaine.¹³⁵ Compounds that block this receptor also attenuate the reinforcing effects of other drugs of abuse.¹³⁶ Although METH and AMPH are similar and share common biochemical and behavioral effects, METH administration increases GLU levels in the PFC to a greater extent compared to AMPH.¹⁰³ The direct consequences of this difference in GLU-releasing ability are not known but may be important in terms of drug-associated neuroplasticity and treatment.

Consistent with the notion that GLU is important in the behavioral effects of METH, compounds that block AMPA-type glutamatergic receptors (NBQX)^{137,138} or NMDA receptors (NPC 12626) decrease METH-induced locomotion. However, only high doses of NPC 12626 that disrupt normal locomotor behavior are effective,¹³⁸ indicating that the METH effects are most likely mediated largely through the AMPA receptor subtype. Similarly, drugs that facilitate removal of METH-induced increases of GLU from the extracellular space block its rewarding effects¹³⁹ as measured by a place conditioning paradigm.¹⁴⁰ The clinical implications for METH-induced increases of GLU in the context of drug abuse are not known. However, current evidence suggests individuals with obsessive-compulsive behavior or disorder (OCD) show hyperglutamatergic activity in the PFC.¹⁴¹ Obsessive-compulsive behavior is akin to uncontrollable drug-seeking and individuals with OCD have an increased likelihood of drug abuse.¹⁴²

6.4.4.4 Novel Therapeutic Targets for METH Addiction

A number of studies have tested compounds that home in on other novel neurotransmitter systems and reveal important clues to the action of METH. Initially classified as an opioid receptor, sigma (σ) receptors (sigma-1 and sigma-2) have been implicated in a variety of psychiatric disorders including depression, anxiety, schizophrenia^{143,144} and, more recently, psychostimulant addiction.¹⁴⁵ Interestingly, sigma receptors are strategically localized in the nucleus accumbens and other areas within limbic circuitry.¹⁴⁵ Studies have demonstrated that psychostimulants bind to sigma receptors¹⁴⁶ and sigma (1) antagonists block many of the behavioral effects of cocaine and AMPH.^{147,148}

Like other psychostimulants, *in vitro* binding studies show that METH also preferentially binds to sigma-1 receptors and pretreatment with sigma-1 receptor antagonists, such as BD1063 or BD1047, attenuates its acute behavioral activating effects.¹⁴⁸ Similarly, antisense oligodeoxynucleotides aimed at sigma-1 receptors, acting as a molecular antagonist, attenuate the locomotor-stimulating effects of METH. Evidence shows that psychostimulants either increase the number or sensitivity of sigma receptors *in vivo* and this also appears to be the case for METH. Indeed, rats previously sensitized to METH are significantly more responsive to the sigma receptor agonist (+)-3-(3-hydroxyphenyl)-N-(1-propyl)piperidine ((+)-3-PPP).¹⁴⁹ Repeated administration of METH increases binding of the sigma ligand [³H](+)-pentazocine in a number of brain areas in rodents.¹⁵⁰ Sigma-1 receptors are also upregulated (protein and mRNA) in rats that self-administer but not in those that passively received METH.¹⁵¹ Most importantly, sigma-1 antagonists block METH-induced behavioral sensitization.^{152,153} The exact mechanism through which sigma-1 receptors are responsible for neutralizing the action of METH is unknown. However, experiments show that sigma-1 receptors mediate cellular restructuring via cholesterol and cytoskeletal trafficking from the endoplasmic reticulum to the plasma membrane and nucleus.^{154,155} It is likely, then, that sigma-1 receptors may be involved in psychostimulant-induced neuroplasticity related to uncontrollable drug intake and by blocking these receptors may interrupt this process.¹⁵⁶ Although details are still emerging, these studies suggest a crucial role for the sigma receptor in the behavioral effects of METH and may prove a useful drug treatment target.

Early studies provided support for an alkaloid (*ibogaine*) found in the root bark of the African shrub *Tabernanthe iboga* having anti-addictive properties. Concerns of toxicity associated with *ibogaine* led to the development of the *iboga* alkaloid congener 18-MC (18-methoxycoronaridine).¹⁵⁷ Experiments in rodents show that 18-MC *enhances* METH-induced locomotion¹⁵⁸ and reduces METH self-administration.¹⁵⁹ These results are consistent with recent reports showing that disulfiram, a clinically efficacious compound for the treatment of cocaine addiction,¹¹⁹ enhances the development and expression of cocaine-induced behavioral sensitization in rats.¹⁶⁰ Binding studies *in vitro* determined that *ibogaine* and 18-HC act as potent antagonists at $\alpha_3\beta_4$ nicotinic acetylcholine receptors with less potency seen at $\alpha_4\beta_2$, NMDA, or 5-HT₃ receptors.¹⁶¹ Drugs such as mecamylamine and dextromethorphan that also antagonize $\alpha_3\beta_4$ block METH self-administration, lending further support for this receptor as a novel therapeutic target.^{161,162} Indeed, lobeline, the lipophilic alkaloid obtained from the herb *Lobelia inflata*, also blocks $\alpha_3\beta_2$ and $\alpha_4\beta_2$ nicotinic neuronal receptors and has demonstrated great potential as a possible treatment for psychostimulant abuse. Lobeline pretreatment inhibits METH-induced locomotion, blocks the discriminative stimulus cue elicited by METH,¹⁶³ and decreases self-administration in rats.¹⁶⁴ Surprisingly, increasing the dosage of METH does not surmount the antagonism by lobeline suggesting good pharmacotherapeutic potential. How lobeline is able to block the powerful reinforcing effects of METH is unknown, although studies indicate that the ability of lobeline to block the METH effects is not due to preventing METH-induced elevations of DA but more likely due to its ability to prevent decreases in VMAT-2 and induction of hyperthermia.⁷⁵ Yet, lobeline also interacts with DAT¹⁶⁵ and increases 5-HT release that may involve SERT and contribute toward its anti-addictive effects.¹⁶⁶ Analogues of lobeline for the treatment of psychostimulant abuse are being developed.¹⁶⁷ Other preclinical studies testing possible novel treatments for METH abuse have targeted GABA,¹⁶⁸ cannabinoid,^{169,170} and histamine receptors.¹⁷¹ As has been attempted for cocaine addiction, a monoclonal antibody vaccine against METH is also in the developmental phase.¹⁷²

6.4.4.5 METH-Induced Alterations in Intracellular Messenger Systems Related to Reinforcement

Recent research has focused on alterations in intracellular messenger systems and regulation of gene expression in response to drugs of abuse.^{173–175} Similar to changes at the neurotransmitter level, molecular alterations occur in areas of the brain that mediate the reinforcing aspects of drug addiction and are long-lasting.¹⁷⁶ Drug-induced alterations are well thought of as a form of neural plasticity.¹⁵⁶ This neural plasticity occurs in response to modified gene expression that eventually leads to changes in neurotransmitter–receptor dynamics. In fact, every major drug of abuse produces long-term neuroplasticity in, for example, the VTA.¹⁷⁷ Understanding these alterations at the cellular level will inevitably improve our understanding of the underlying neural adaptations that govern addiction.

The first intracellular pathway to be thoroughly examined in the context of drug abuse was the cAMP/PKA/CREB cascade.¹⁷⁸ Neurotransmitters or drugs that activate D₁ receptors facilitate (acting through G_{as} stimulatory G proteins) whereas neurotransmitters or drugs that activate D₂ (acting through G_{oi} inhibitory G proteins) decrease the formation of cyclic adenosine 3,5-monophosphate (cAMP). cAMP, in turn, affects cAMP-dependent protein kinase (PKA). The formation of cAMP is dependent on adenylyl cyclase and is degraded by various phosphodiesterase enzymes in the cytoplasm.¹⁷⁹ Drugs of abuse alter the dynamics of this intracellular messenger system. For example, repeated psychostimulant administration results in decreases in inhibitory G proteins (G_{oi}) linked to D₂ receptors,^{180,181} and elevated tyrosine hydroxylase^{181–183} in the VTA. A number of persistent neuroadaptations are seen in the NAC in response to drug exposure. These include psychostimulant induced supersensitivity of D₁-mediated effects,¹⁸⁴ decreased levels of G_{oi}, but no effect on G_s G proteins,^{185,186} increased adenylyl cyclase, cAMP-dependent protein kinase (PKA),¹⁸⁵ and immediate-early gene expression of fos-associated proteins such as Δ FosB.^{187–189} Enhancing cAMP activity

in the VTA potentiates psychostimulant sensitization and inactivation of PKA blocks this effect.¹⁹⁰ Infusion of cAMP analogues, Rp- and Sp-cAMPS, bilaterally into the NAC, that block and facilitate PKA, respectively, induce and prevent relapse of cocaine seeking behavior.¹⁹¹ Of primary importance is recent work on cAMP-response element-binding protein (CREB), a transcription factor localized in the nucleus that plays a crucial role in gene expression and plasticity associated events.^{192,193} CREB has been implicated in a number of behavioral processes in particular, drug-induced sensitization,¹⁹⁴ and reinforcement.^{175,195,196}

Elevating cAMP/PKA levels in the NAC enhances, whereas blocking PKA attenuates, the expression of cocaine-induced locomotor sensitization.¹⁹⁷ Likewise, recent reports demonstrate that the behavioral activating effects of METH can be antagonized by indirectly increasing cAMP levels with rolipram, a selective inhibitor of cAMP-specific phosphodiesterase 4 that degrades cAMP.¹⁹⁸ Co-treatment with systemic rolipram (4 mg/kg) blocks METH-induced activation in rats following a sensitizing treatment regimen (4 mg/kg \times 5 days, 1 week withdrawal, then a 2 mg/kg METH challenge). Rolipram does not alter METH-induced increases in extracellular levels of DA in the striatum suggesting that the antagonism of the behavioral effects of METH were most likely due to increases in cAMP.¹⁹⁹ These data are in complete agreement with Mori et al.^{199a} showing rolipram co-treatment blocks METH and morphine's locomotor activating effects but not those elicited by phencyclidine. The authors found that very high doses of rolipram (10 mg/kg) only partially attenuated SKF81297-induced (D_1 agonist) locomotion. Therefore, these data suggest that METH effects were likely blocked by increasing cAMP through inhibitory D_2 receptors. Post-mortem findings in METH abusers support this notion (see below).

Activated through the D_1 receptor pathway, DA and cAMP-regulated phosphoprotein 32kDa (DARPP-32) is a substrate for PKA found in the striatum and is involved in molecular adaptations that occur in response to drugs of abuse.²⁰⁰ Phosphorylation by PKA converts DARPP-32 into an efficient inhibitor of PP1 (protein phosphatase-1). Consistent with the known fact that psychostimulants alter cellular responses acutely and long-term, PP1 has been shown to modulate AMPA channels involved in neuronal plasticity.^{201–203} Once activated by PKA, however, DARPP-32 then affects a variety of downstream physiological effectors.²⁰⁰ Studies in genetically modified mice lacking DARPP-32 show altered responses to psychostimulants.^{204,205} Like cocaine, acute METH administration (20 mg/kg) increases DARPP-32 immunoreactivity and phosphorylation of various residues associated with GLU receptor subtypes in the neostriatum in wild-type but not in DARPP-32 knockout mice.²⁰⁶ This effect was also shown *in vitro* and *in vivo* in the striatum of rats sensitized to METH.^{207,208} DARPP-32 is also phosphorylated by a cyclin-dependent kinase (cdk5) that reverts the protein into a PKA inhibitor.²⁰⁹ Interestingly, intra-NAC injections of roscovitine, a cdk5 inhibitor, attenuates METH-induced locomotor sensitization.²⁰⁸ Moreover, recent evidence has connected cdk5 with Δ FosB, a transcription factor implicated in long-term adaptations to drugs of abuse.²¹⁰ However, whether METH induces the expression of Δ FosB is not known. METH also affects ARPP-21, a cAMP-regulated phosphoprotein of 21 kDa that is also phosphorylated by PKA and enriched in limbic structures.²¹¹ Acute administration of METH or cocaine increases ARPP-21 phosphorylation in rodents.²¹² What role these proteins play in METH-induced behavioral effects such as reinforcement is unclear.

Intracellular signaling is heavily dependent on Ca^{2+} , and drug-induced alterations could have profound effects on normal neuronal function. Indeed, chronic METH decreases kinases associated with Ca^{2+} such as Ca^{2+} /calmodulin (CaM)-dependent protein kinase II (CaM-kinase II) specifically in the VTA-NAC pathway that is blocked by the D_1 antagonist SCH23390 and MK801, a GLU antagonist.^{213,214} Other Ca^{2+} -associated proteins are also affected by METH, for example, calmodulin, a calcium-binding protein also implicated in the effects of other drugs of abuse.²¹⁵ Similar to the effects seen on CaM-kinase II, chronic METH (4 mg/kg \times 14 days, 28 day withdrawal and a 4mg/kg challenge) significantly decreases calmodulin mRNA in the NAC and VTA. Comparable decreases have been seen in calcineurin in the striatum of rats sensitized to METH.²⁰⁷ It is not known, however, whether these decreases affect neuronal function in a manner associated with

drug sensitization or reinforcement. However, reduced activity of Ca^{2+} proteins involved in intracellular trafficking would undoubtedly have effects on several substrate proteins that are important for proper neuronal functioning.

Experiments conducted *in vitro* using immunofluorescence and mobility shift assays reveal that acute application leads to accumulation of METH in cytosol and vesicular compartments (4 to 6 h) and eventual translocation into the nucleus. In the nucleus, METH increases activator protein-1 (AP-1) and CREB DNA binding activity.^{216,217} Pre-incubation with an anti-METH antibody prevents the enhancement of these DNA-binding proteins.²¹⁸ Experimental evidence shows that METH-evoked enhancement of AP-1 and CREB binding but not of other transcription factors (NF- κ B, SP-1, STAT1, STAT3) is dose-dependent and is apparent in brain areas involved in reinforcement such as the frontal cortex and hippocampus.²¹⁹ METH (4 mg/kg) administration for 2 weeks with a 1 week interval and a final challenge — a treatment that produces drug sensitization — results in significant increases in cFos, CREB, and pCREB (phosphorylated form of CREB) immunoreactivity in rat striatum.²²⁰ Animals learn preferences for places (place preference) where they have previously experienced a reward. Drugs that are more rewarding induce robust place preferences. In contrast, drugs that are not rewarding may produce aversion.²²¹ Recent studies show that CREB plays a primary role in the rewarding effects of psychostimulants. For example, Carlezon et al.^{221a} demonstrated using viral transfer techniques that overexpression of CREB in the NAC makes cocaine aversive whereas blocking CREB enhances the rewarding attributes of the drug. Whether modulating CREB in the NAC will alter METH-induced reward is not known.

While the role of molecular adaptations in response to drugs of abuse affecting the cAMP/PKA/CREB signaling cascade has been thoroughly investigated, less attention has been paid to other intracellular pathways. For example, the mitogen-activated protein kinase (MAPK) pathway plays an important role in cell growth, differentiation, proliferation,²²² and neural plasticity associated with learning and memory.²²³ Evidence suggests that drug-induced maladaptive forms of neural plasticity in areas of the brain involved in reward learning^{101,156} may underlie the uncontrolled drug-seeking and drug intake seen in addiction.²²⁴ For example, changes in plasticity-related genes in response to METH include tissue plasminogen activator,²²⁵ activity-regulated cytoskeleton-associated protein,²²⁶ synaptophysin, and stathmin²²⁷ and MAP kinase phosphatases.²²⁸ A number of other gene-products associated with this pathway are altered in METH-induced sensitized animals.²²⁹ METH-evoked expression of genes involved in neuronal remodeling in limbic brain areas could contribute to drug-reward processes. For example, a number of studies in rodents implicate MAPK pathway in psychostimulant-induced sensitization and reward learning.^{230–232} Consistent with these results, Mizoguchi et al.^{232a} provide definitive evidence involving MAPK and METH-induced reward conditioning. Results show hyperphosphorylation of MAPK/ERK1/2 in the NAC and striatum but not in other areas in rats that had previously undergone METH-induced place conditioning. Pretreatment with both D_1 (SCH23390) and D_2 (raclopride) antagonists and PD98059 (a selective MAPK inhibitor) directly infused into the NAC blocks METH-induced place preference conditioning and ERK1/2 activation. This suggests a critical involvement of the MAPK/ERK signaling cascade in METH-evoked reward learning.

6.4.4.6 METH-Induced Alterations in Intracellular Messenger Systems in Humans

Results from post-mortem human studies addressing METH-induced changes in receptors and intracellular messenger systems are generally in line with changes seen in animal studies (Figure 6.4.1). For example, inhibitory G proteins, $\text{G}_{\alpha i1}$ and $\text{G}_{\alpha i2}$, and $\text{G}_{\alpha o}$ levels are reduced (32 to 49%) in the NAC of METH (and heroin) abusers.²³³ These results are consistent with rodent studies showing that cocaine and heroin decrease inhibitory G protein levels in the NAC.^{185,186} Experiments exploring the effects of METH specifically on G protein levels have not been conducted in animals. Although the lower inhibitory G protein levels could represent a preexisting deficit it is more likely that they are the result of neural adaptations employed to restore balance in response to chronic

Figure 6.4.1 Hypothetical schematic diagram depicting cellular changes in the NAC based on post-mortem analysis of human brain. Normally, DA stimulates D₁ receptors coupled to the G_s G protein that stimulates the formation of cAMP via adenylyl cyclase (AC). The D₂ receptor is coupled to the inhibitory G_i G protein that inhibits the formation of cAMP by AC. Accumulation of cAMP frees the catalytic subunits of cAMP-dependent protein kinase (PKA) to enter the nucleus and phosphorylate CREB. Most all drugs of abuse alter this cascade to an extent. Although evidence is limited, methamphetamine abusers show increased D₁ receptor protein levels and decreased DA stimulated AC (indicated by the increased and reduced size, respectively). D₂ receptor protein levels are marginally decreased and G_i and G_{oo} G proteins are significantly decreased in METH abusers. These changes may represent adaptations aimed at regaining homeostasis. Decreases in D₂ receptors and inhibitory G proteins may compensate for overstimulation with METH-induced supraphysiological levels of extracellular DA. Increased D₁ receptor levels could also be considered compensatory for the cellular effects rendered through overstimulated D₂ receptors. However, D₁-stimulated AC activity is impaired in human METH abusers. These results indicate possible downregulation or tolerance in both pathways by different mechanisms.

METH stimulation. Inhibitory G proteins are linked to a number of receptors including D₂. A compensatory down-regulation of the D₂ receptor pathway, or D₂ receptors specifically, is consistent with imaging studies showing that this receptor is significantly decreased in METH abusers.²³⁴ Moreover, D₁ receptor protein is significantly increased, whereas D₂ receptors are marginally decreased in the NAC of METH abusers.²³⁵ The increase in D₁ receptors could also be part of the compensatory homeostatic mechanism engendered to oppose overstimulation of the D₂ pathway. Indeed, this scenario is supported by findings in a number of animal studies.^{179,185,191} Yet, although total D₁ receptor protein is increased, evidence shows that DA stimulation of adenylyl cyclase activity is decreased by 25 to 30% in the NAC of human METH abusers.²³⁶ These results call for caution in predicting functional abnormalities based on receptor and G protein concentrations. Additional studies in human brain are needed to further characterize intracellular neuroadaptive changes in the addicted state.

6.4.5 Neurotoxicity Associated with METH Consumption

Evidence from rodent, nonhuman primate, and post-mortem human studies indicates that METH is highly toxic to the CNS. This section briefly reviews neurotoxicity associated with METH abuse with particular attention on monoamines. Excellent and detailed reviews have been published elsewhere.^{77,237–242}

METH-evoked neurotoxicity in the striatal DA system has been characterized in a number of species. For example, acute and chronic administration leads to striatal DA depletion, damaged nerve terminals,^{243–246} and altered DAT,^{64,243,247,248} tyrosine hydroxylase,^{249,250} and VMAT.^{76,251,252} The

hyperthermic-inducing effects of METH play a role in toxicity. Experiments in rats show that blocking METH-facilitated increases in body temperature⁶⁶ is neuroprotective^{253,254} perhaps by decreasing damage caused by reactive oxygen species formed from supraphysiological levels of extracellular DA.⁶⁶ Further, evidence indicates that terminal regions of the nigrostriatal DA system are especially susceptible to the toxic effects of METH,²⁵⁵ whereas the VTA–NAC reward pathway is less affected.²⁵⁶ Similar to DA, acute and chronic METH exposure decreases tryptophan hydroxylase, SERT, and depletes 5-HT.^{82,251}

Analogous to most rodent studies, nonhuman primate studies show METH-induced deficits in DAT, VMAT, and DA.^{256–258} Interestingly, long-term experiments indicate that some of these effects reverse over time^{259,260} particularly when METH dosage regimen resembles the “binge”-like intake patterns seen in humans. Correspondingly, rodent and primate studies suggest that metabolite parameters in DA and 5-HT neurotransmitter systems and behavior appear to normalize over time; however, the extent of recovery depends on dose and length of drug exposure.^{259,261–264}

Post-mortem human studies *partially* confirm preclinical findings in animals. METH abusers have decreased striatal tyrosine hydroxylase, DA, and DAT in the NAC and striatum.²⁶⁵ Yet pre-synaptic markers VMAT and DOPA decarboxylase are not altered.²⁶⁶ These findings suggest that there is no permanent damage to neurons in humans and confirms the results of one study in monkeys showing that nigral cell bodies are preserved following recovery.²⁵⁵ However, evidence from imaging studies indicate, no matter the length of time of recovery, deficits remain²⁶⁷ (see below). A number of factors, however, may explain these discrepant results between animal and post-mortem studies such as dose, duration of abuse, young vs. old population, and past drug histories. Taken together, post-mortem evidence supports that the human brain is susceptible to METH-induced alterations in DAergic parameters.

6.4.5.1 Oxidative Stress: A Possible Cause of METH-Induced Neurotoxicity

The exact mechanisms responsible for METH-induced neurotoxicity have not been fully defined. As mentioned previously, however, a large body of work implicates oxidative stress inflicted by reactive oxygen species in damaging neurons. Although GLU plays a significant role in the destructive effects of METH,²⁶⁸ it is clear that excess DA is required for neurotoxicity to occur. Reactive species can form from oxidation of DA, DA auto-oxidation, and disruption of mitochondria.⁷⁷ Pretreatment with DA-synthesis inhibitors prevents METH-induced damage in both DA and 5-HT systems and L-dopa reverses this effect.^{82,269–271} METH administration also induces the formation of an endogenous neurotoxin 6-hydroxydopamine (6-OHDA), used experimentally to induce DA-specific lesions.^{272,273} Further, studies in genetically modified mice have shown that the degree of damage is mediated, in part, by a number of enzymes. Mice over-expressing the reducing enzyme superoxide dismutase (SOD) show reduced METH-induced neurotoxicity.^{274–277} In contrast, mice devoid of the reactive-species-producing enzyme nitrous oxide synthase are resistant to the toxic effects of METH.²⁷⁸ METH abnormally redistributes DA into the oxidizing environment of the neuron's cytoplasm from the reducing environment of the synaptic vesicles leading to possible damage to the neuron. Support for this assumption comes from experiments in which mice lacking the VMAT-2, which sequesters DA into synaptic vesicles, show exacerbated METH-induced damage in the DA system.²⁷⁹ Also consistent with this notion, antioxidants including ascorbic acid,²⁸⁰ vitamin E,²⁷⁴ nicotinamide,²⁸¹ melatonin,^{282,283} and selenium^{284–286} attenuate METH-induced neurotoxicity.

6.4.5.2 METH-Induced Effects in Human Brain: Imaging Studies

Advances in imaging techniques have furthered our knowledge of the neural circuits involved in addiction. Positron emission tomography (PET), single photon emission tomography (SPECT), and function magnetic resonance imaging (fMRI), among others, allow measurement of relevant neuropharmacological parameters in the living brain. Recent studies using these techniques in

METH abusers reveal a number of abnormalities. For example, a PET [^{18}F]fluorodeoxyglucose (a marker of brain glucose metabolism) study in detoxified METH abusers showed hypermetabolism in the parietal cortex and hypometabolism in the striatum (caudate and putamen) suggesting a dysregulation between DAergic and non-DAergic mechanisms.²⁶⁷ Compared to controls, current METH abusers undergoing a vigilance task exhibit lower metabolism in areas of the brain implicated in mood (anterior cingulate, insula and orbitofrontal area, middle and posterior cingulate, amygdala, ventral striatum, and cerebellum) as also measured by PET [^{18}F]fluorodeoxyglucose.²⁸⁷ Two additional SPECT $^{99\text{m}}\text{Tc}$ -hexamethylpropylene-amine-oxime (HMPAO) studies corroborated with PET results show abnormal perfusion profiles in METH abusers.^{288,289} Greater thalamic but not striatal (caudate and NAC) metabolism is apparent in METH abusers abstinent <6 months compared to 12 to 17 months.²⁹⁰ The persistent decrease in striatal metabolism suggests long-lasting changes. Consistent with findings in post-mortem human brain, individuals with METH abuse histories have significant decreases in binding of the PET DAT radioligand [^{11}C]WIN-35,428 in the caudate and putamen.²⁹¹ Other PET studies using compounds targeting the DAT have confirmed decreased DAT binding in the caudate and putamen in current abusers,²⁹² recently detoxified subjects,²⁹³ and in those abstinent for upwards of 11 months.²³⁴ Studies have also linked abnormalities in D_2 receptors and substance abuse given that lower levels are found in alcoholics,²⁹⁴ and cocaine²⁹⁵ and heroin²⁹⁶ abusers. In line with these data, D_2 receptor levels are lower in the caudate and putamen of METH abusers, as measured by PET [^{11}C]raclopride²⁶⁷ (but see Reference 293). Taken together, these data clearly show abnormal brain function in METH abusers. Future studies are needed to determine permanent neurochemical deficits through longitudinal studies and possible therapies to reverse these deficits.

6.4.6 Conclusions

METH continues to be a major public health concern in the U.S. and other parts of the world. The dramatic increase in METH patient admissions and untoward effects on social, community, and familial sectors underscores the need for effective treatments. Yet despite significant advances in our understanding of the neurobiological mechanisms that govern its addictive properties, effective pharmacotherapies have not emerged.^{297,298} Long-term social support and pharmacological treatments aimed at relieving the protracted anhedonia, dysphoria, anxiety, severe craving from METH withdrawal, and maladaptive drug-seeking are badly needed. Campaigns to alert the health care community of the importance in identification and proper treatment of the METH-addicted patient are paramount. It is hoped that further studies on the neurobiology of METH bring a clearer understanding of the mechanisms that underlie its deleterious effects.

6.5 NEUROCHEMICAL ADAPTATIONS AND COCAINE DEPENDENCE

Kelly P. Cosgrove, Ph.D. and Julie K. Staley, Ph.D.

Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut and the VA Connecticut Healthcare System, West Haven, Connecticut

Cocaine addiction is a disease of the brain that is characterized by compulsive drug-taking behavior that may be a consequence of an altered neurochemical state. Cocaine use by inhalation or injection produces a rapid, intense, euphoric “rush,” which leads to repeated use. The repeated use of cocaine causes long-lasting changes in brain receptors and transporters that perpetuate drug use and the resulting dysphoria or depression. Furthermore, regulatory changes in neurochemical targets that have occurred as a compensatory response to “oppose” or “neutralize” the pharmacological effects of the drug persist after the drug has cleared from the brain, and may underlie the craving and dysphoria associated with cocaine withdrawal and relapse. Revolutionary advances in basic neuroscience have catalyzed extraordinary efforts toward the discovery and development of novel central nervous system (CNS) drugs effective for the treatment of cocaine dependence. These advances have included the molecular cloning and characterization of many of the receptors and transporters implicated in the rewarding effects of and dependence on cocaine. Understanding how and which receptors and transporters are altered by chronic cocaine use may identify targets for the development of drugs that will alleviate the symptoms associated with the initiation and perpetuation of drug-taking behavior. Current drug discovery efforts have taken multiple approaches toward the development of cocaine pharmacotherapies.

Many of the novel pharmacological agents currently under development are directed toward a single molecular target related to or regulated by cocaine. Some pharmacotherapies currently under evaluation are directed toward multiple distinct receptor and/or transporter populations known to modulate the activity of the drug reward circuit. Several approaches have been taken to develop medications to treat cocaine dependence. Cocaine “substitute” medications are drugs that act via a similar mechanism as cocaine but with a more limited abuse potential. This strategy seeks to alleviate some of the withdrawal effects and reduce craving and is similar to nicotine replacement therapy for tobacco smoking or methadone maintenance for heroin addiction. Cocaine antagonists block the effects of cocaine or block the binding of cocaine to the dopamine transporter and thus attenuate the reinforcing effects of cocaine and reduce the likelihood of cocaine use. This is similar to naltrexone therapy for heroin addiction in which naltrexone, a mu-opioid receptor antagonist, blocks the binding of heroin or other opiates to the mu-opioid receptor. This strategy may also target other receptor systems that modulate dopaminergic activity to functionally antagonize the effects of cocaine. The cocaine vaccine interferes with the pharmacokinetics of cocaine by blocking or slowing cocaine’s uptake into the brain, thus eliminating its reinforcing effects. Thus far, several promising treatments have been developed yet no truly effective medications exist and none is approved specifically for the treatment of cocaine dependence. This chapter reviews recent research studies that have identified neurochemical targets regulated by chronic cocaine use and their implications for the development of pharmacotherapies for cocaine dependence.

6.5.1 Neurochemistry of Cocaine Dependence

Many drugs with abuse liability including cocaine have been shown to enhance dopaminergic neurotransmission in the mesolimbic drug reward circuits. Cocaine, an indirect-acting dopaminergic agonist, binds to recognition sites on the plasma membrane dopamine (DA) transporter and increases dopamine levels by preventing the reuptake of released dopamine.^{1–3} Intravenous injection of cocaine has been shown to significantly inhibit dopamine reuptake within 4 s.⁴ The reinforcing effects of cocaine are initiated by the interactions of dopamine with pre- and postsynaptic DA receptors. Two classes of DA receptors have been classified including the D₁ receptor family (D₁, D_{1a}, and D₅/D_{1b} receptor subtypes) and the D₂ receptor family (D₂, D₃, and D₄ receptor subtypes).⁵ The DA receptor subtypes are distinguished by their distinct anatomical, molecular, pharmacological, and signal transduction properties.⁵ When cocaine is present, extracellular dopamine levels are elevated resulting in chronic stimulation of the DA receptors.³ This persistent interaction of dopamine with its receptors alters the DA receptor signaling, which may, in part, underlie the reinforcing properties of cocaine.³ Furthermore, postsynaptic DA receptors have been localized to other neurotransmitter-containing pathways including GABAergic, glutamatergic, and cholinergic projections indicating that additional neurochemical pathways may undergo compensatory adaptive changes in response to the persistent activation of DA receptors. The effects of cocaine in brain are widespread in the mesolimbic system including the ventral tegmental area, ventral striatum, and prefrontal cortex.

Recently, considerable evidence has accumulated suggesting that other neurochemical substrates (i.e., glutamatergic, serotonergic, GABAergic, and opioidergic) also play a role in the development of cocaine dependence. The anatomical organization of these neurochemical systems within the drug reward circuit suggests that functional interactions may occur between dopaminergic systems and neighboring neural pathways. Nigrostriatal dopaminergic neurons and corticostriatal glutamatergic neurons colocalize on common GABAergic medium spiny dendrites in the striatum suggesting the potential for interdependency between the two circuits.⁶ Glutamate antagonists that act at the NMDA receptor complex block stereotypy and locomotor activation in animal models of cocaine dependence indicating that the glutamatergic pathway may be critical to the expression of these psychomotor stimulant behaviors.^{6,7} Serotonergic projections to the ventral tegmental area

input onto dopamine cell bodies suggesting that serotonin modulates mesolimbic DA neurotransmission by direct stimulation (i.e., cocaine increases extracellular serotonin by blocking reuptake) or by indirect modulatory feedback mechanisms from DA nerve terminal activation.⁸ Mesolimbic DA neurotransmission is modulated in part by tonic activation of the μ - and κ -opioid receptors located in the vicinity of the DA cell bodies and DA nerve terminals, respectively. Activation of μ -opioid receptors in the ventral tegmental area increases dopamine release in the nucleus accumbens, whereas activation of the κ -opioid receptors in the nucleus accumbens inhibits dopamine release.^{9–11} Cross-talk between opioids, serotonin, glutamate, GABA, and dopamine may lead to a sequence of neuroadaptive processes that contribute to the behavioral and physiological manifestations associated with cocaine dependence. Additionally, understanding of the neuroadaptive changes involved in cocaine dependence may lead to the development of effective medications for the treatment of the disorder.

6.5.2 DA Transporter and Cocaine Dependence

6.5.2.1 Regulation of the Dopamine Transporter (DAT) by Cocaine

The addictive liability of cocaine and other DA-enhancing psychostimulants may be related to compensatory adaptation of the dopamine transporter (DAT) to chronic elevations of intrasynaptic DA. The DAT is a protein on neuronal membranes that is involved in synaptic transmission by transporting DA from the extracellular space to the neuron.¹² There is a wealth of evidence suggesting that cocaine mediates its powerful reinforcement by binding to recognition sites on the DAT. Interestingly, mice lacking the DAT (DAT-KO) still self-administer cocaine¹³ and show cocaine-induced conditioned place preference,¹⁴ indicating that cocaine exerts strong reinforcing effects via alternative neurotransmitter systems. Persistent inhibition of DA reuptake by cocaine has been shown to alter the number of cocaine recognition sites associated with the DAT. Chronic treatment of rats with intermittent doses of cocaine resulted in a two- to fivefold increase in the apparent density of [³H]cocaine and [³H]BTCP binding in the striatum.¹⁵ Significant increases in striatal [³H]WIN 35,428 binding were observed in rats allowed to self-administer cocaine in a chronic unlimited access paradigm,¹⁶ rats treated intermittently and continuously with cocaine,¹⁷ and rabbits treated with intermittent cocaine injections.¹⁸ Chronic cocaine exposure in nonhuman primates resulted in significantly increased DAT binding sites compared to binding in drug-naïve control monkeys in the ventral striatum measured with [³H]WIN 35,248.¹⁹ Consistently, in post-mortem brain from human cocaine users, striatal DAT binding sites were significantly increased compared to controls using [³H]WIN 35,248.^{20,21} DAT densities detected using [¹²⁵I]RTI-55 and [³H]WIN 35,248 were elevated throughout the caudate, putamen, and nucleus accumbens of cocaine-related deaths²² and fatal cocaine overdose victims (Figure 6.5.1).^{22–25} Furthermore, Rosenthal plots of the saturation binding data demonstrated that the increase of [³H]WIN 35,428 binding observed in the cocaine overdose victims was due to an elevation in the apparent density of the high-affinity cocaine recognition site on the DAT.²⁴ While most studies indicate chronic cocaine results in increased DAT binding sites, some have reported a decrease²⁶ or no change.²⁷ Further, it was reported that administration of GBR 12909 (also called vanoxerine) but *not* cocaine resulted in a decrease in DAT density in caudate putamen and nucleus accumbens²⁸ highlighting that while GBR 12909 is a selective DA reuptake blocker, cocaine's effect involves other transporter systems. Importantly, elevations in DAT demonstrated in the post-mortem brains of human cocaine abusers are supported by *in vivo* SPECT imaging in human cocaine-dependent subjects.²⁹ Here, the striatal uptake of [¹²³I]β-CIT (also called RTI-55) was significantly elevated (25%) in acutely abstinent (≥ 96 h) cocaine-dependent subjects. These studies suggest that the high-affinity cocaine binding sites are upregulated in the striatal reward centers with chronic cocaine use as a compensatory response to elevated synaptic levels of DA. It was hypothesized that this upregulation of cocaine recognition sites associated with

Figure 6.5.1 Visualization of the distribution of the DA transporter, D_3 receptor, and κ_2 -opioid receptor in the human brain of a drug-free control subject and a representative cocaine overdose victim. (A, B) The DA transporter was measured using [3H]WIN 35,428 (2 nM) as described previously. (C, D) The D_3 receptor was measured using [3H](+)-7-OH-DPAT (1 nM) in the presence of GTP (300 mM) to enhance the selective labeling of the D_3 receptor subtype over the D_2 receptor subtype as described previously. (E, F) The κ_2 -opioid receptor subtype was measured using [^{125}I]IOXY on tissue sections pretreated with BIT and FIT to occlude binding to the μ - and δ -opioid receptors, respectively.

the DAT may reflect an increased ability of the protein to transport DA. As the transporter elevates its apparent density in the nerve terminal to clear DA from the synapse, more cocaine will be needed to experience cocaine's reinforcing effects and euphoria.²⁴ This neuroadaptive regulation of the DAT may occur as a result of the direct interaction of cocaine with the DAT, or, alternatively, may be due to feedback mechanisms that are activated as a consequence of prolonged elevation concentrations of DA. Recent evidence suggests that chronic cocaine may also lead to increased DAT function. Mash and colleagues³⁰ reported increased [3H]WIN 34,428 binding and [3H]dopamine uptake in post-mortem human striatal synaptosomes from cocaine addicts compared to age-matched controls, indicating that chronic cocaine functionally upregulates DAT. Additionally, evidence from cell cultures suggests that the increase in DAT transport activity from chronic cocaine may be due to the concurrent increase in DAT cell surface expression.^{31,32} The direct regulation of DAT by cocaine suggest that the DAT is an ideal target for the development of anti-cocaine medications.

6.5.2.2 Rate of Interaction of Cocaine with the DAT and Cocaine Reinforcement

An alternative neurochemical hypothesis for the reinforcing efficacy of cocaine at the DAT is related to the rate of entry of cocaine into the brain, coupled with its ability to rapidly bind to the DAT, inhibit DA uptake, and enhance dopaminergic neurotransmission.³ This hypothesis is based on the knowledge that other drugs known to block DA uptake, such as mazindol, GBR 12909, and methylphenidate, are not as reinforcing as cocaine³³ and exhibit a slower rate of entry into the brain and a slower onset of action.³⁴ Furthermore, GBR 12909, methylphenidate, bupropion, and mazindol displace the *in vivo* binding of the radiolabeled cocaine congener [³H]WIN 35,428 at a considerably slower rate than cocaine.³⁵ In humans, methylphenidate demonstrates a lower abuse liability as compared to cocaine, but enters the CNS with a rate similar to cocaine. An *in vivo* study determined that the potency of methylphenidate vs. cocaine at the DAT is similar and thus unlikely to underlie the differences in abuse potential.³⁶ However, methylphenidate is cleared more slowly than cocaine and has a longer duration of side effects, and both factors may underlie its decreased rate of administration and abuse liability.³⁷ Imaging studies have shown that, in general, while the level of DAT blockade is important in determining the intensity of the euphoric effects or “high,” the rate at which substances block DAT determines the perceived “high.”³⁸ For example, in monkeys, a PET study showed that cocaine and GBR 12909 affected DA synthesis and DAT availability with different time courses; e.g., GBR 12909 decreased [¹¹C]β-CFT binding for a longer time than did cocaine.³⁹ These studies suggest that pharmacological interventions that decrease the rate of entry into or clearance of cocaine from the brain, or alternatively block or slow cocaine’s interaction with the DA transporter may be useful for the treatment of cocaine dependence.

6.5.2.3 The DAT as a Target for Cocaine Pharmacotherapies

One pharmacotherapy strategy for the treatment of cocaine dependence that has received significant attention is the development of drugs that antagonize or substitute for cocaine at its site of action in the brain.^{40,41} Hypothetically, the “ideal cocaine antagonist” would manifest high-affinity binding to cocaine recognition sites on the DAT, slow dissociation from these binding sites, minimal inhibition of substrate binding and uptake, a long biological half-life, and low abuse liability.^{40–42} The DA reuptake inhibitor, GBR 12909 appears to satisfy several of these criteria.^{40–42} At low doses, GBR 12909 binds to the DAT with high affinity, dissociates slowly, causes only a modest increase in extracellular DA, and partially antagonizes the increase in extracellular DA evoked by local perfusion of cocaine into the striatum and the nucleus accumbens.^{40,41} However, at high doses, GBR 12909 produces locomotor activation, stereotypy, behavioral sensitization, and cross-sensitizes with cocaine.⁴² Importantly, behavioral studies indicate that GBR 12909 reduces cocaine-maintained behaviors in rats⁴³ and in nonhuman primates.⁴⁴ The dose of GBR 12909 that reduced cocaine self-administration in rhesus monkeys⁴⁴ was quantified *in vivo* in baboon and results indicated that GBR 12909 must occupy at least 50% of DAT to translate into behavioral efficacy, e.g., reduce responding for cocaine.⁴⁵ This is consistent with the finding that doses of cocaine that are reliably self-administered by rhesus monkeys occupy 53 to 87% of DAT.⁴⁶ These studies suggest that the development of a cocaine antagonist is plausible; however, efficacy as a cocaine antagonist may be dose-related. At some doses GBR 12909 has also been shown to *increase* or reinstate cocaine-seeking behavior,⁴³ but it is unclear whether this would translate into high abuse liability in a human clinical population. Other DAT inhibitors that have been shown to reduce the self-administration of cocaine in animals include PTT, RTI 113, and HD-23.^{47–49} Molecular characterization studies of DAT, which used chimeric dopamine-norepinephrine transporters, delineated discrete domains for substrate and cocaine interactions.^{50,51} These studies support the development of a cocaine antagonist devoid of uptake blockade activity for the clinical management of cocaine addiction. Current drug discovery efforts have focused on the development of compounds

using cocaine as the core structure, in an effort to find a drug that blocks cocaine interactions with the DAT, but does not block the normal uptake function of the transporter. While these studies are in the early stages, it is anticipated that this approach may lead to the development of an efficacious anti-cocaine medication.

6.5.2.4 Cocaine Vaccines

An alternative pharmacotherapy for cocaine dependence currently under investigation is use of a cocaine vaccine to blunt the reinforcing effects of cocaine.^{51–60} The basis of this pharmacotherapy is to decrease the rate of entry of cocaine into the CNS (and therefore the onset of action), by either binding cocaine with antibody generated by active immunization with a stable cocaine conjugate or by using an enzymatically active antibody specific for cocaine.

Because cocaine is a small molecule (MW = 303 g/mol) it is unlikely that it will be immunogenic and therefore must be conjugated to a carrier molecule such as KLH (keyhole limpet hemocyanin), polyethylene glycol, diphtheria, or tetanus toxoids to enhance its immunogenicity.^{53–55} While early attempts to make a cocaine vaccine did not demonstrate significant efficacy for blocking the effects of cocaine in the CNS,⁵⁵ recent studies have been more successful.^{56,57} Active immunization with a stable cocaine-KLH conjugate lowered cocaine levels in the brain by 80% in immunized vs. control rats, enough to decrease cocaine-induced hyperlocomotion and stereotypic behavior.⁵⁶ However, while the active immunization approach to cocaine pharmacotherapy appears promising, its success will be hindered if the addict administers large enough quantities of cocaine to override the antibody-induced blockade.⁵⁷ Active immunization with the cocaine immunogen GNC-KLH significantly reduced cocaine-induced reinstatement in rats and resulted in an eightfold rightward shift in the cocaine dose–effect curve, indicating that surmountability of the vaccine occurred at a dose of cocaine that was eight times higher than a dose necessary to maintain cocaine responding.⁶¹ Subsequently, a second-generation hapten 3 (GND) was synthesized and, in rats, active immunization with GND-KLH resulted in robust decreases in cocaine-induced ambulatory and stereotypic behaviors.⁶²

Use of a catalytic cocaine antibody may bypass this potential downfall of the active immunization approach. The enzymatically active catalytic cocaine antibody cleaves cocaine into two inactive metabolites: ecognine methyl ester and benzoic acid. The two metabolites are released from the catalytic antibody rendering the antibody free to degrade more cocaine. Because the catalytic antibodies are not depleted, it is impossible for the cocaine abuser to “override” the presence of the antibody by administering higher doses of cocaine.⁵⁸ Catalytic antibodies have been generated against transition state analogues of cocaine^{58–60} and a catalytic antibody was shown to reduce cocaine-induced toxicity and block the self-administration of cocaine in rats.⁶³ While this strategy to blunt the reinforcing effects of cocaine is promising, the antibody will not alleviate the craving, dysphoria, anxiety, or depression often linked to relapse. Thus, although the cocaine antibodies may prevent cocaine reinforcement, they will not block the reinforcing effects of other psychostimulants that an addict may administer to relieve withdrawal symptoms.⁶⁴ In addition, the success of the catalytic antibody may be hindered if the antibody is perceived as foreign, and idiotypic antibodies are produced that will interact with the cocaine antibody, rendering it enzymatically inactive.

The safety of the cocaine vaccine TC-CD in former cocaine abusers has been evaluated in a Phase I clinical trial, and it was determined that the vaccine was well tolerated with dose-related increases in antibody levels.⁶⁵ Two Phase II clinical trials have now been conducted.^{66,67} The vaccine was again well tolerated and subjects reported a reduction in cocaine’s reinforcing effects. The antibody levels were detectable after the second dose, peaked at 8 to 12 weeks, and remained elevated for up to 6 months; preliminary findings indicated a negative association between antibody level and cocaine use. Other anti-cocaine vaccines in development include a blocking antibody (ITAC-cocaine) and a monoclonal catalytic antibody (15A10).

6.5.3 DA Receptors and Cocaine Dependence

The rewarding effects of dopamine are mediated by five DA receptor subtypes distinguished by their unique molecular and pharmacological properties and distinct anatomical locations. Repeated and prolonged elevations in synaptic dopamine levels that result from the binge use of cocaine may result in alterations in the affinity, number, or coupling state of the DA receptors. At present, the relative contribution of each of the DA receptor subtypes to the rewarding effects of cocaine is not clear. Dopamine agonists that interact with receptors belonging to both the D₁ and D₂ receptor families function as positive reinforcers, while both D₁-like and D₂-like receptor antagonists decrease the reward value of psychostimulants.^{68,69} Stimulation of D₁ or D₂ receptors in the ventral tegmental area enhances the rewarding effect for brain stimulation.⁷⁰ These findings suggest that compensatory changes in DA receptor number or signaling may contribute to the development of cocaine dependence.

6.5.3.1 Cocaine-Induced D₁ Receptor Adaptations

The reinforcing effects of cocaine are mediated, in part, by the D₁ receptors in the nucleus accumbens and the central nucleus of the amygdala.⁷¹ In preclinical animal studies, administration of the D₁ receptor antagonist SCH 23390 prevents reinstatement to cocaine-induced conditioned place preference,⁷² reduces reinstatement to cocaine-seeking behavior,⁷³ and SCH 23390 when administered in combination with cocaine prevents the development of cocaine sensitization.^{74,75} While cocaine self-administration is increased in the presence of D₁ receptor antagonists,^{68,76–79} which is likely a compensatory response, it has recently been demonstrated that, under some schedules of reinforcement, low doses of benzazepine D₁ receptor antagonists block cocaine self-administration.⁸⁰ Additionally, a variety of D₁ receptor agonists (SKF 82958, SKF 81297, SKF 83959) and an antagonist (ecopipam) reduced reinstatement of cocaine-seeking in nonhuman primates.⁸¹ Further, SCH 23390 reversed the attenuating effects of SKF 81297 on cocaine-seeking behavior but not cue-induced reinstatement in rats⁸² indicating that the reductions in cocaine-seeking behavior are not due simply to behavioral disruption. These findings suggest that the state of the D₁ receptor population may dictate the ability of D₁ receptor antagonists to enhance or to block the reinforcing effects of cocaine. D₁ receptor mRNA levels, receptor number, and receptor sensitivity are altered as a consequence of protracted cocaine exposure and may, in part, account for some of the D₁ receptor-mediated behavioral responses to cocaine. D₁ receptor mRNA is not altered in the striatum, nucleus accumbens, or substantia nigra of human cocaine abusers;⁸³ however, elevations in D₁ receptor mRNA were observed in the striatum of rats chronically treated with cocaine.⁸⁴ The D₁ receptor is also critical for mediating cocaine-induced expression of certain genes (the *fos* and *Jun* family immediate early genes which encode transcription factors) and molecules such as brain-derived neurotrophic factor, β -catenin, and G α olf, which are implicated in mediating cocaine's actions in the nucleus accumbens and caudate putamen.⁸⁵ Increased D₁ receptor density was reported in the nucleus accumbens and olfactory tubercle in rat brain following twice-daily injections of cocaine.⁸⁶ Chronic cocaine treatment results in an adaptive increase in D₁ receptor number in olfactory tubercle, nucleus accumbens, central pallidum, and substantia nigra, which normalized within 1 day⁸⁷ and remained at baseline values for up to 3 days⁸⁸ and 30 days⁸⁹ after cocaine treatment. Conversely, decreased striatal D₁ receptor densities that persisted for at least 2 weeks after the last administration of cocaine have been observed.⁸⁴ Chronic cocaine exposure in monkeys resulted in increased D₁ receptor density in striatum.⁹⁰ Electrophysiological sensitivity of D₁ receptors in the nucleus accumbens neurons is enhanced in rats 2 weeks post-cocaine administration,^{91,92} suggesting that despite the number of D₁ receptors detected, adaptation in the D₁ receptor signaling cascade may occur to enhance D₁-receptor-mediated dopamine transmission. When these findings are viewed collectively, it is difficult to ascertain precisely the regulatory adaptations that the D₁ receptor undergoes in response to

protracted cocaine use. The differences may be due to a variety of factors including variations in dose, frequency, and route of administration. These factors have been shown to influence the adaptive responses of dopaminergic synaptic markers; therefore, the differences may be attributed to distinct drug administration protocols.¹⁷ Regardless of the adaptive response observed, it is evident from these studies that the adaptations of the D₁ receptor may be integral to the development of cocaine dependence and therefore may be a useful target for the development of cocaine pharmacotherapies.

6.5.3.2 Cocaine-Induced Adaptations in D₂ Receptors

The actions of cocaine on D₂ receptors have been shown to be essential to the development of cocaine dependence. The D₂ receptor antagonist haloperidol inhibits the development of behavioral sensitization to cocaine.⁷⁴ Sensitization is believed to play an important role in drug craving and the reinstatement of compulsive drug-taking behavior;^{93,94} thus, altered regulation of D₂ receptors may contribute to the reinforcing potential of cocaine. D₂ mRNA levels were not altered in the striatum of human cocaine abusers⁸³ or rats treated with cocaine.^{95,96} D₂ receptor mRNA levels were decreased in the olfactory tubercle of rats treated with a single injection of cocaine,⁹⁵ whereas D₂ receptor mRNA levels were transiently elevated in rats treated chronically with cocaine.⁸⁴ A transient increase in the binding of [³H]raclopride in the olfactory tubercle and rostral nucleus accumbens and caudate-putamen was observed after binge administration of cocaine⁹⁷ and elevations in [³H]spiperone and [¹²⁵I]spiperone binding were seen in the nucleus accumbens, olfactory tubercle, and substantia nigra after intermittent cocaine administration.⁸⁷ In contrast, D₂ receptor densities were not significantly affected in the rat striatum 3 days post-cocaine administration.⁸⁸ In monkeys, chronic cocaine exposure resulted in a significant decrease in D₂ receptor density throughout the striatum measured with [³H]raclopride.⁹⁰ Furthermore, [¹⁸F]N-methylspiroperidol labeling in living cocaine abusers demonstrated decreased D₂ receptor densities after a 1 week detoxification⁹⁸ and quantitative immunoblotting of post-mortem brain samples demonstrated a decrease in protein levels of D₂ receptors in the nucleus accumbens of cocaine users compared to controls.⁹⁹ Viewed collectively, these studies suggest that the D₂ receptor may undergo a transient elevation in the response to acute cocaine administration, which normalizes upon cocaine abstinence. However, caution should be taken in the interpretation of these data because these radioligands do not discriminate between D₂ and D₃ receptors and, therefore, identity of the regulated D₂ receptor subtype is not known.

6.5.3.3 Cocaine-Induced Adaptations in D₃ Receptors

Cocaine-induced adaptations at the D₃ receptor may mediate some of the reinforcing effects of cocaine. D₃ receptor-preferring agonists, although not self-administered by drug-naïve monkeys, are self-administered by monkeys previously trained to self-administer cocaine.¹⁰⁰ D₃ receptor-preferring agonists substitute for the discriminative stimulus effects of cocaine and produce place preference in rats and monkeys indicating that the D₃ receptor may mediate some of the subjective effects of cocaine.^{101–103} These studies suggest that adaptations in the affinity, density, or molecular expression of the D₃ receptor induced by chronic cocaine use may underlie, in part, the development of cocaine dependence.

The D₃ receptor-preferring agonist [³H]-(+)-7-OH-DPAT has been used in quantitative *in vitro* autoradiography studies to assess the status of D₃ receptors in human cocaine overdose (CO) victims¹⁰⁴ (Figure 6.5.1). Binding of [³H]-(+)-7-OH-DPAT was elevated one- to threefold in the nucleus accumbens and ventromedial sectors of the caudate and putamen in CO victims as compared to drug-free and age-matched control subjects. D₃ receptor/cyclophilin mRNA ratios were also increased sixfold in the nucleus accumbens in CO vs. control subjects indicating that cocaine exposure effects D₃ receptor mRNA expression. These findings were confirmed by saturation

analysis of the [^3H]-(+)-7-OH-DPAT binding in membranes from the nucleus accumbens. The affinity for [^3H]-(+)-7-OH-DPAT binding was not different in the CO victims or the “Excited Delirium” (ED) victims as compared to drug-free control subjects. However, the saturation binding density for the CO victims (4.4 ± 0.4 pmol/g) when compared to the drug-free control subjects (3.1 ± 0.2 pmol/g) was significantly elevated.¹⁰⁵

Interestingly, after 1-day withdrawal from chronic treatment with cocaine, increased D_3 receptor densities were observed in the striatum, while decreased D_3 receptor densities were observed in the nucleus accumbens of the rat brain.¹⁰⁶ In another study D_3 receptor binding was increased in the nucleus accumbens and ventral caudate putamen at 31 days after the last cocaine delivery but not at the 2-day or 8-day time points compared to controls.¹⁰⁷ Additionally, the density of D_3 receptors was increased in animals exposed to cocaine-associated stimuli.¹⁰⁸ It should be noted, however, that in the first study mentioned¹⁰⁶ the densities of the D_3 receptors were high in the dorsal striatum, as compared to the nucleus accumbens, which contrasts with the intense localization of the D_3 receptor mRNA in the nucleus accumbens of rat and human brain^{109,110} and the higher D_3 receptor densities in the ventral striatum and the nucleus accumbens of the human brain.¹⁰⁵ In another study, D_3 receptor mRNA expression was not altered in human cocaine abusers.¹¹¹ These findings suggest that D_3 receptor mRNA and binding sites may be differentially regulated by cocaine exposure. A single cocaine exposure was recently shown to increase brain-derived neurotrophic factor (BDNF) mRNA in the prefrontal cortex of rats and was associated with a long-lasting increase in D_3 mRNA and D_3 protein in the nucleus accumbens.¹¹² Chronic treatment of C_6 glioma cells transfected with the D_3 receptor cDNA with DA agonists increased D_3 receptor densities, but did not change D_3 mRNA abundance.¹¹³ The upregulation in D_3 receptor densities was blocked by treatment with cycloheximide, suggesting that the increase was mediated by increased protein synthesis. Changes in proteins, mRNA, and BDNF in addition to changes in D_3 density are likely associated with long-lasting cocaine-conditioned and cocaine-seeking behavior.

Alternatively, increased [^3H]-(+)-7-OH-DPAT binding may reflect a selective increase in one of the D_3 receptor isoforms. The D_3 receptor specific probes may have hybridized to multiple alternative splice variants, including the truncated D_3 receptors.¹¹⁴ Because DAergic ligands do not bind to the proteins generated from the truncated splice variants, regulation of message levels and binding site densities would be dissociated. The relative abundance of specific D_3 receptor isoforms may vary also with alterations in DA neurotransmission. While the biological significance and function of the D_3 receptor splice variants are not understood, it has been suggested that alternative splicing may regulate the relative abundance of the different D_3 receptor isoforms to differentially modulate D_3 receptor-mediated signaling.¹¹⁵ Therefore, it may be suggested that the elevation in D_3 receptor density after chronic cocaine use may reflect a selective increase in one of the D_3 receptor isoforms. Additional studies are needed to determine if this regulatory pattern occurs in the human brain. D_3 receptor adaptations that result from repeated activation of the DA neurotransmission due to chronic “binge” use of cocaine may contribute to the development of cocaine dependence. This adaptive increase in the D_3 receptor may enhance the reinforcing effects of cocaine and contribute to the development of cocaine dependence. Recent development of potential *in vivo* agents for imaging the D_3 receptor in living humans will advance our understanding of the role of D_3 receptors in cocaine dependence.¹¹⁶

6.5.3.4 DA Receptors as Targets for Cocaine Pharmacotherapies

The search for pharmacotherapies for cocaine dependence has focused on drugs that target the DA receptors. Cocaine’s reinforcing properties result from its ability to prolong the action of dopamine at the DA receptors in brain reward regions.³ From this perspective it has been suggested that DA antagonists may block cocaine use by preventing the interaction of dopamine with its receptors, and therefore block reinforcement. In animal self-administration studies, both D_1 receptor (SCH 23390^{68,76}) and D_2 receptor antagonists (pimozide,^{117,118} sulpiride,¹¹⁸ chlorpromazine,¹¹⁹ spip-

erone,⁷⁶ metoclopramide,¹¹⁸ pherphenazine¹²⁰) increase cocaine self-administration by decreasing the reinforcing potential of cocaine. However, recent studies have shown that low doses of benzazepine D₁ receptor antagonists attenuate cocaine self-administration under certain schedules of reinforcement.⁸⁰ These findings suggest that certain doses of D₁ receptor antagonists may be efficacious for the treatment of cocaine dependence. Flupentixol, a dopamine antagonist with high affinity for the D₁ receptor, has demonstrated some efficacy for decreasing craving and increasing treatment retention in human cocaine abusers.¹²¹ D₂ receptor antagonists (haloperidol and chlorpromazine) have been efficacious for the treatment of paranoia and psychosis but not craving in human cocaine abusers.^{122,123} D₂ receptor antagonists also elicit significant adverse side effects such as abnormal movements and are not effective at reducing cocaine use even at high doses.¹²⁴ While DA antagonists may block the reinforcing efficacy of cocaine, use of DA antagonists as pharmacotherapies may be hampered by their propensity to enhance cocaine withdrawal symptoms.⁶⁴ Furthermore, compliance is hindered by the dysphoric and extrapyramidal side effects associated with the blockade of DA neurotransmission.¹²⁵

DA receptor agonists also have been suggested as anti-cocaine medications because of their propensity to reduce craving that occurs during cocaine withdrawal. A recent study using pergolide, a D₂/D₃ receptor agonist, has demonstrated some efficacy for decreasing craving.¹²⁶ Bromocriptine, a D₂-like agonist, has undergone extensive evaluation as a treatment for cocaine dependence and appears to reduce craving in cocaine abusers.¹²⁷ However, its efficacy as a pharmacotherapy for cocaine dependence was weak.¹²⁸ Furthermore, studies using an indirect-acting DA agonist, amantadine, were not as successful as anticipated.¹²⁹ The poor outcome of these studies, which were conducted in the late 1980s, may be explained by a recent preclinical study which demonstrated that D₂-like agonists actually enhance cocaine-seeking behavior or “prime” the addict to initiate another binge use of cocaine^{125,130} and D₂ receptor agonists are typically no longer developed as potential medications for cocaine dependence. However, cabergoline, a long-acting D₂ receptor agonist, has recently been evaluated in a Phase II trial for cocaine dependence and was more effective than placebo in reducing cocaine use as measured by negative urine screens for cocaine metabolites.¹³¹ D₁-like agonists oppose cocaine-seeking behavior induced by cocaine itself¹³⁰ suggesting that D₁-like receptor agonists may be efficacious for the treatment of craving in cocaine dependence. However, while D₁-like agonists may attenuate the craving associated with cocaine withdrawal and relapse and may not enhance cocaine-seeking behavior, they may be reinforcing and therefore at risk to be abused themselves.

The close association of the D₃ receptor with the striatal reward pathways and its selective distribution in the mesolimbic dopamine system suggests that drugs that target the D₃ receptor subtype may decrease the reinforcing effects of cocaine. Because D₃ receptors’ densities elevate as cocaine dependence develops, this upregulation of D₃ receptors may contribute to the reinforcing effects of cocaine.¹⁰⁵ From this perspective, the development of drugs that block D₃ receptor function may be useful for the treatment of cocaine dependence. In keeping with this hypothesis, the D₃-selective antagonists (–)DS 121¹²⁵ and SB-277011A¹³² attenuate cocaine self-administration in rats and block cocaine reinstatement.^{133,134} Alternatively, agents that act as D₃ agonists or partial agonists may be used as substitutes to treat cocaine dependence.¹³⁵ The compound BP 897, a highly selective D₃ agonist, reduced cocaine seeking behavior in rats;¹³⁶ however, BP 897 also demonstrates antagonist properties at human D₃ and D₂ receptors,¹³⁷ suggesting that the cocaine-reducing effects may be due to antagonism at these sites. While these studies are encouraging, additional research is necessary to confirm the efficacy of either D₃ receptor antagonists or agonists as clinically useful pharmacotherapies. Several other agents that act within the dopamine system are being evaluated in clinical trials. These include disulfiram, which may act by increasing brain levels of dopamine and decreasing levels of norepinephrine, selegiline, which is an irreversible MAO inhibitor, and reserpine, a Rauwolfia alkaloid currently used as an antihypertensive agent, which acts to deplete dopamine, norepinephrine, and serotonin in presynaptic vesicles; see Gorelick et al.¹³⁸ for review.

6.5.4 Kappa-Opioid Receptors

The endogenous opioidergic system has been implicated as a primary mediator of the behavioral and reinforcing effects of cocaine.⁹⁴ (See Reference 139 for more information on the interaction of cocaine with the opioid system including the μ - and δ -opioid receptors). Pharmacological and molecular cloning studies have recently reported the existence of at least three subtypes of κ -opioid receptors.^{140–147} Receptor mapping studies have demonstrated that both κ_1 -opioid receptor and κ_2 -opioid receptor subtypes are prevalent throughout the mesocorticolimbic pathways in the human brain.^{26,148,149} One striking difference in the localization of the two subtypes is reflected by the intense localization of the κ_2 -opioid receptor subtype in the ventral or “limbic” sectors of the striatum and the nucleus accumbens in the human brain.¹⁴⁹ Conversely, the κ_1 -opioid receptor subtype may preferentially localize to the dorsal or “sensorimotor” areas of the human striatum.²⁶ Based on their neuroanatomical distribution in the human striatum, it may be hypothesized that the κ_1 -opioid receptor subtype modulates motor functions, while the κ_2 -opioid receptor subtype mediates emotional behaviors and affect. The anatomical localization of the κ -opioid receptor subtypes and their intimate association with dopaminergic reward pathways suggests that regulatory alterations in both κ_1 - and κ_2 -opioid receptors may be important in cocaine dependence.

6.5.4.1 Regulation of Kappa-Opioid Receptors by Cocaine

At present, the functional significance and relevance of each of the κ -opioid receptor subtypes in the CNS and their role in modulating the brain reward pathways with chronic substance abuse is not well understood. An adaptive increase in the density of κ -opioid receptors in guinea pig brain after chronic cocaine treatments was detected using the κ_1 -selective radioligand [³H]U69,593.¹⁵⁰ Furthermore, elevations in [¹²⁵I]Tyr¹-D-Pro¹⁰-dynorphin A binding to κ -opioid receptors were observed within the dorsal and “motor” sectors of the striatum of human cocaine abusers.²⁶ Dynorphin A demonstrates higher affinity to the κ_1 -opioid receptor subtype as compared to the κ_2 -opioid receptor subtype; therefore, it may be suggested on the basis of occupancy that the elevated binding of [¹²⁵I]Tyr¹-D-Pro¹⁰-dynorphin A observed in these studies may be due to recognition of the κ_1 -opioid receptor subtype.^{147,151,152} These findings combined with animal behavioral studies (e.g., cocaine place preference and self-administration) suggest a definitive role for the κ -opioid receptor in cocaine dependence. While these studies are reasonably conclusive, other studies are not, due to the use of radioligands, which lack selectivity between κ -opioid receptor subtypes. After chronic continuous exposure to cocaine,¹⁵³ elevated binding of the nonselective opioid agonist and antagonist ([³H]bremazocine and [³H]naloxone, respectively) were observed in the nucleus accumbens. Thrice daily injections of cocaine in rats resulted in increased κ -opioid receptor density in cingulate cortex, nucleus accumbens, and caudate putamen.⁸⁶ Furthermore, in rats treated with cocaine using a binge-administration paradigm, binding of [³H]bremazocine to κ -opioid receptors was increased.¹⁵⁴ Binding density of [³H]U-69593, a selective κ -opioid receptor ligand, was significantly higher in caudate putamen and nucleus accumbens after chronic cocaine infusion¹⁵⁵ indicating increased numbers of κ -opioid receptors in brain areas associated with drug craving and reward.

It is interesting that in the same animal model, κ -opioid receptor mRNA was decreased in the substantia nigra, but not in the ventral tegmental area of cocaine treated rats.¹⁵⁶ A recent study also reported κ -opioid receptor mRNA levels are decreased after cocaine self-administration in rats in the nucleus accumbens and ventral tegmental area.¹⁵⁷ The reasons for this disconnect between κ -opioid receptor binding and the κ -opioid receptor mRNA are not known. However, the discrepancy may be due to the detection of multiple κ -opioid receptor mRNAs or binding sites or to the binding of the [³H]bremazocine to a κ -opioid receptor subtype distinct from the κ -opioid receptor message that was measured. While the interpretation of these studies with regards to which κ -opioid receptor subtype was measured and the regulation of each subtype by cocaine is difficult at this time, recent

advances in the cloning of these receptor subtypes and the development of subtype-specific radioligands will clarify these issues in the near future.

Recently, pharmacological binding assays to selectively label the κ_2 -opioid receptor subtype have been developed using the opioid antagonist [125 I]IOXY in the presence of drugs occluding binding to the μ - and κ -opioid receptor subtypes.¹⁵¹ This strategy was used in ligand binding and *in vitro* autoradiography assays to assess the regulation of the κ_2 -opioid receptor subtype after cocaine exposure in post-mortem human brain (death was from cocaine overdose) (Figure 6.5.1).^{149,158} Quantitative region-of-interest densitometric measurements of [125 I]IOXY binding demonstrated a twofold elevation in the anterior and ventral sectors of the caudate and putamen and in the nucleus accumbens of human cocaine overdose victims as compared to drug-free and age-matched control subjects. In subjects who experienced paranoia and agitation prior to their death, κ_2 -opioid receptors were also elevated in the amygdala.^{104,158}

The regulation of κ_2 -opioid receptor numbers in the striatal reward centers suggests that adaptations in the κ_2 -opioid receptors may also contribute to the development of cocaine dependence. κ -opioid agonists do not generalize to cocaine cues in drug discrimination paradigms;^{159,160} however, κ -opioid agonists suppress the stimulus effects of cocaine in monkeys.¹⁶¹ Therefore, it is unlikely that κ -opioid receptors play a direct role in the stimulus of euphoric effects of cocaine. The elevation of the κ_2 -opioid receptor subtype along with its discrete localization to the “limbic” or “emotional” striatum indicates that compensatory adaptation in this subtype may underlie the “affective” or “emotional” effects associated with cocaine dependence. Shippenberg and colleagues¹⁶² have suggested that “conditioned aversive effects” associated with hyperactivity of κ -opioidergic neurons in the ventral striatum may underlie the “motivational incentive” to use cocaine. Furthermore, the subjective effects of κ -opioid agonists mimic the symptoms of cocaine withdrawal suggesting that excessive activity of the opioidergic system may, in part, contribute to the aversive effects associated with cocaine withdrawal. Because protracted exposure to cocaine alters the DA-mediated reward systems, κ -opioidergic systems may undergo adaptations in an effort to re-establish the balance between the reward system and the opposing aversive system. However, when cocaine is withdrawn and the dopaminergic reward circuit is no longer activated, the κ_2 -opioid receptor numbers may remain elevated, and may contribute to the unpleasant feelings and dysphoria associated with withdrawal from cocaine.

6.5.4.2 Kappa-Opioid Receptor Drugs as Cocaine Pharmacotherapies

There is considerable evidence supporting a critical role for κ -opioid receptors in the development of cocaine dependence. Co-administration of κ -opioid agonists with cocaine inhibits cocaine self-administration,¹⁶³ cocaine-induced place preference,¹⁶² and the development of sensitization to the rewarding effects of cocaine.^{93,94,164} In rats, U-69593, a κ -opioid receptor agonist, reduced cocaine self-administration and cocaine seeking behavior¹⁶⁵ and the reinstatement to cocaine self-administration.¹⁶⁶ Further, daily administration of the mixed κ -opioid antagonist and partial μ -opioid agonist buprenorphine reduces cocaine self-administration by rhesus monkeys¹⁶⁷ and prevents the reinstatement of cocaine-reinforced responding in rats.¹⁶⁸ κ -opioid agonist drugs such as bremazocine also reduce cocaine self-administration in rhesus monkeys.^{169,170} These potent anti-cocaine effects exhibited by κ -opioid receptor agents in preclinical animal studies suggest that κ -opioid receptors may be a useful target for the pharmacotherapeutic treatment of cocaine dependence. One κ -opioid agonist, enadoline, has recently been examined in clinical trials. While the drug was well-tolerated it did not reduce the acute subjective effects in a laboratory study.¹⁷¹ Buprenorphine has demonstrated some efficacy in decreasing cocaine abuse in heroin abusers^{172,173} and the combination of buprenorphine and naloxone, a μ -opioid antagonist, is currently used for the treatment of heroin and other opiate addiction.¹⁷⁴ As a medication for cocaine addiction, buprenorphine has been studied in cocaine abusers with concurrent opioid dependence and was found to reduce cocaine use.¹⁷⁵ The development of pharmacotherapeutic κ -opioid agonists has

been hindered by reports that, in humans, administration of κ -opioid agonists elicits aversive and psychotomimetic effects.^{176–178} The recent identification of multiple subtypes of κ -opioid receptors with distinct pharmacological and molecular properties^{140–147} has led to the hypothesis that different κ -opioid receptor subtypes may mediate distinct actions of κ -opioid agonists.^{151,152,178} Therefore, it may be possible to develop κ -opioid drugs that lack and/or inhibit the dysphoric properties and yet maintain efficacy for blocking cocaine administration. At present, distinct “sensorimotor” vs. “limbic” striatum may, in part, mediate the feelings of dysphoria and craving associated with cocaine withdrawal distress. The similarity between symptoms associated with cocaine withdrawal and the subjective effects of kappa-opioid agonist administration suggests that increased activity in the kappa opioid receptor system during cocaine withdrawal may underlie the dysphoric effects. The extent that the κ_2 -opioid receptor subtype specifically mediates the dysphoric properties of κ -opioid agonists will not be known until selective κ_2 -opioid agonists are developed. However, if the κ_2 -opioid receptor does not mediate dysphoria during cocaine withdrawal, then selective κ_2 -opioid receptor antagonists may be useful for the treatment of the dysphoria that underlies relapse and the perpetuation of cocaine misuse.

6.5.5 Serotonin Transporter and Cocaine Dependence

Cocaine binds with high affinity to the serotonin (5-HT) transporter and inhibits 5-HT uptake.^{2,179} Serotonergic neurons project from the dorsal raphe to the ventral tegmental area where they modulate mesolimbic DA neurotransmission. Inhibition of 5-HT uptake in the dorsal raphe nucleus by cocaine decreases the firing of the raphe neurons by feedback activation of the 5-HT_{1A} autoreceptors,^{180–182} an effect that is blocked by pretreatment with a 5-HT synthesis inhibitor p-chlorophenylalanine.¹⁸¹ With chronic cocaine treatment, these mechanisms become sensitized probably as a result of a compensatory upregulation of [³H]imipramine binding to the 5-HT transporter in the dorsal raphe, frontal cortex, medial, and sulcal prefrontal cortex of cocaine treated rats.¹⁸² These studies suggest that adaptations in the serotonergic neurotransmission may contribute in part to the expression of cocaine-induced behaviors. While an enhancement of serotonin neurotransmission is believed to be inhibitory to the expression of cocaine-mediated behaviors or to have minimal effect,^{183,184} there is some evidence that 5-HT may play a role in the mood-elevating effects of acute cocaine. Interestingly, depletion of tryptophan (the precursor to 5-HT) severely attenuated the subjective high experienced by cocaine-dependent subjects.¹⁸⁵ Furthermore, withdrawal from chronic cocaine use has been associated with symptoms of depression¹⁸⁶ due to cocaine-induced alterations in 5-HT neurotransmission.¹⁸⁷ Together, these studies suggest that regulatory alterations in serotonergic signaling play a role in cocaine dependence. Furthermore, drugs that antagonize these alterations in serotonergic systems may be efficacious for the treatment of cocaine dependence.

6.5.5.1 The 5-HT Transporter as a Target for Cocaine Pharmacotherapy

The effects of cocaine may be antagonized by 5-HT-mediated inhibition of mesolimbic DA neurotransmission.¹⁸⁸ Thus, increased 5-HT neurotransmission that results from blocking presynaptic 5-HT uptake may decrease cocaine administration. In keeping, preclinical animal studies have demonstrated that enhancement of serotonergic neurotransmission by administration of the selective 5-HT uptake inhibitors citalopram and fluoxetine attenuates the discriminative stimulus effects of cocaine in monkeys.¹⁸⁹ Furthermore, fluoxetine inhibits cocaine self-administration¹⁹⁰ and reduces the breakpoints on a progressive ration schedule reinforced by cocaine.¹⁹¹ Conversely, depletion of 5-HT enhances cocaine self-administration.¹⁹² Several 5-HT reuptake inhibitors have been evaluated for the treatment of cocaine dependence. Fluoxetine significantly decreased subjective ratings of cocaine's positive mood effects on several visual analog measures and attenuated the mydriatic effect of cocaine in human cocaine abusers.¹⁹³ Fluoxetine has been suggested to decrease craving and cocaine use in methadone-maintained cocaine users.^{194–196} While the efficacy of fluoxetine may

be related to its ability to reduce craving,^{197,198} it is likely that its effects are more related to its ability to reverse the symptoms of depression that are associated with cocaine withdrawal. Another 5-HT transporter inhibitor, sertraline, was not shown to be more effective than placebo in reducing cocaine use in recent clinical trials.¹⁹⁹

6.5.6 Glutamate Receptors and Cocaine Dependence

There is increasing evidence supporting a role for glutamate receptors including the NMDA (*N*-methyl-D-aspartate) and AMPA receptors in the neural and behavioral changes resulting from chronic cocaine administration.⁷ Glutamate is the major excitatory neurotransmitter found mainly in cortical and limbic neurons, which project to the nucleus accumbens. Preclinical studies with the noncompetitive NMDA receptor antagonist MK-801 have linked excitatory glutamatergic synapses with the development of cocaine sensitization, a cardinal feature of cocaine dependence. Simultaneous administration of low doses of MK-801 prevented the development of sensitization to the stereotypic and locomotor stimulant effects of cocaine.^{200–205} Alternatively, when MK-801 was administered prior to cocaine, the stimulating effects of cocaine were enhanced.²⁰⁶ The competitive NMDA antagonist CPP partially prevented the development of cocaine sensitization.²⁰⁴ MK-801 decreased the incidence of seizures and mortality caused by cocaine.^{207–209} The AMPA receptor antagonist NBQX produced dose-dependent decreases in cocaine-induced locomotor stimulation.²⁰³ Dopaminergic neurons in the ventral tegmental area of cocaine-treated rats were more responsive to glutamate while nucleus accumbens neurons were less sensitive.²¹⁰ Cortical NMDA receptors are upregulated after cocaine treatment²¹¹ and GluR1 (an AMPA receptor subunit) and NMDAR1 (an NMDA receptor subunit) are upregulated in the ventral tegmental area²¹² suggesting that compensatory adaptation of the glutamate receptors may result from or contribute to enhanced glutamatergic neurotransmission. Alterations in the mesocorticolimbic glutamate transmission may in part contribute to the development of cocaine sensitization.²¹⁰ Recent evidence suggests that neuroadaptative changes in amygdaloid glutamate receptors, which are involved in cocaine seeking and craving, are apparent during cocaine withdrawal.²¹³

6.5.6.1 Glutamate Receptors as Targets for Cocaine Pharmacotherapies

Since NMDA receptors mediate the development of sensitization to cocaine's reinforcing effects, they may serve as a target for cocaine pharmacotherapies.²¹⁴ However, while both competitive and noncompetitive NMDA receptor antagonists block the development of cocaine sensitization, they appear to be ineffective once sensitization has developed. NMDA receptor antagonists do not alter the acute stimulant effects of cocaine.^{7,200} Acute pretreatment with MK-801 caused a loss of discriminative responding; however, it did not block cocaine self-administration.²¹⁴ Furthermore, many drugs that act at the NMDA receptors produce phencyclidine-like behavioral effects.²⁰³ Together, these preclinical studies do not offer significant support for NMDA receptor antagonists as cocaine pharmacotherapies. However, AMPA receptor antagonists do not appear to produce phencyclidine-like behavioral effects, and they block cocaine-induced locomotor stimulation. While additional preclinical studies are necessary, it has been suggested that non-NMDA glutamate receptor antagonists, such as agents acting at the metabotropic glutamate receptor 5 (mGluR5), may be a target for the development of pharmacotherapies for the treatment of cocaine dependence.

6.5.7 GABA Receptors and Cocaine Dependence

The GABAergic system in concert with the dopaminergic and glutamatergic systems are involved in cocaine addiction. Dopamine and glutamate terminals synapse on GABA spiny cells in the brain reward area of the nucleus accumbens²¹⁵ and there are GABA projections to the nucleus accumbens.²¹⁶ There are many similarities in the projections of dopamine and GABA

suggesting that GABA may modulate the effects of cocaine within the dopaminergic system. For example, treatment with the dopamine agonist pramipexole was associated with increased GABA levels in the prefrontal cortex of cocaine dependent subject after 8 weeks of treatment.²¹⁷ Additionally, acute cocaine use increased dopamine together with increased GABA transmission in the prefrontal cortex,²¹⁸ while repeated cocaine use decreased dopamine D₂ receptor and GABA_B receptor function.²¹⁹ These changes could ultimately result in lower GABA levels in cocaine-dependent individuals, and, therefore, medications that increase GABA levels may be useful in treating cocaine addiction.

6.5.7.1 GABA Receptors as Targets for Cocaine Pharmacotherapies

Preclinical and clinical studies have examined the effects of GABA agents on cocaine-seeking behaviors. In animals, gamma-vinyl gamma-aminobutyric acid (GVG), a GABA agonist, reduced cocaine self-administration,²²⁰ and a combination of muscimol, a GABA_A agonist, and baclofen, a GABA_B agonist, blocked the reinstatement of cocaine²²¹ and decreased cocaine self-administration.^{222,223} In humans, the GABA agonists topiramate,²²⁴ tiagabine,¹⁹⁹ and baclofen²²⁵ decreased cocaine use. Baclofen has also been shown to reduce limbic activation in response to cocaine craving.²²⁵ The use of GABA_B agonists as treatments has been slowed by the adverse side effects including sedation and motor impairment. Recently, positive allosteric modulators at the GABA_B receptor have been developed, which do not have intrinsic activity but interact with already present GABA to enhance its effect.²²⁶ Further research is necessary to determine whether GABA receptor agonists, positive allosteric GABA modulators, or possibly a combination will be clinically useful.

6.5.8 Multitarget Pharmacotherapeutic Agents

Many of the novel pharmacotherapeutic agents currently under development are directed toward a single molecular target related to cocaine or known to be regulated by cocaine. Although this strategy has been somewhat beneficial, the development of an effective treatment for cocaine dependence may require multisite targeting of distinct neuroreceptor populations that are known to modulate the activity of the drug reward circuit. Cocaine interacts with at least three distinct neurochemical systems in the brain including the dopaminergic, serotonergic, and noradrenergic systems. Cocaine enhances the neurotransmission of each of these systems by blocking the pre-synaptic reuptake. Chronic perturbations of monoaminergic neurotransmission that result from protracted use of cocaine may, in turn, alter cholinergic and glutamatergic neurotransmission by indirect actions. The ability of cocaine to alter signaling of multiple neurochemical pathways in the brain suggests that a multitarget pharmacotherapy may be an optimal approach for the treatment of cocaine dependence.

6.5.8.1 Ibogaine: The Rain Forest Alkaloid

Ibogaine, the principal alkaloid of the African rain forest shrub *Tabernanthe iboga* (Apocynaceae family), is currently being evaluated as an agent to treat psychostimulant addiction.²²⁷ Anecdotal reports of ibogaine treatments in opiate-dependent or cocaine-dependent humans describe alleviation of drug “craving” and physical signs of opiate withdrawal after a single administration of ibogaine, which in some subjects contributes to drug-free periods lasting several months thereafter. This has recently been confirmed in a preliminary study reporting that ibogaine significantly reduced craving for both cocaine and heroin and significantly improved depressive symptoms in an inpatient detoxification setting.²²⁸ In drug self-administration studies, ibogaine and related iboga alkaloids reduced intravenous self-administration of cocaine 1 h after treatment. This suppression on cocaine intake was evident 1 day later, and in some rats a persistent decrease was noted for as long as several weeks.²²⁹ Ibogaine also effectively blocks morphine self-administration²²⁹ and reduces

preference for cocaine consumption in a mouse cocaine-preference drinking model.²³⁰ And, cocaine-induced stereotypy and locomotor activity were significantly lower in ibogaine-treated mice.

The mechanism of action for ibogaine may be resolved in part by defining high-affinity pharmacological targets for ibogaine. The receptor binding profile for ibogaine suggests that multiple neurochemical pathways may be responsible for ibogaine's anti-addictive properties. Ibogaine binds to μ - and κ_1 -opioid receptors, α -1 adrenergic receptors, M_1 and M_2 muscarinic receptors, serotonin 5-HT₂ and 5-HT₃ receptors, and voltage-dependent sodium channels with micromolar affinities.²³¹ Ibogaine completely displaced [³H]MK-801 binding^{232,233} and blocked NMDA-depolarizations in frog motor neurons.²³³ Ibogaine demonstrated moderate affinity for binding to cocaine recognition sites on the DA transporter²³¹ and on the 5-HT transporter.²³⁴ Ibogaine, which blocks access of cocaine to the DA transporter, may²³⁵ or may not restrict substrate uptake.²³⁶ Because ibogaine displays lower affinity for the DA transporter compared to cocaine, it may meet some of the criteria for the "ideal cocaine antagonist."

The anti-addictive properties of ibogaine may, in part, be mediated by a pharmacologically active metabolite. Recently, the principal metabolite of ibogaine was isolated from biological specimens of subjects administered ibogaine using GC/MS.^{234,237} The metabolite that results from *O*-demethylation of the parent drug was identified as 12-hydroxyibogamine (noribogaine). Preliminary pharmacokinetic studies have suggested that noribogaine is generated rapidly and exhibits a slow clearance rate.²³⁴ The relatively long half-life of noribogaine suggests that the long-term biological effects of ibogaine may, in part, be mediated by its metabolite. Similar to ibogaine, noribogaine binds to the μ - and κ_1 -opioid receptors with micromolar potency.^{238,239} The most striking finding has been the demonstration that noribogaine binds to the cocaine recognition site on the 5-HT transporter with a nanomolar potency,^{234,239} and elevates extraneuronal 5-HT in a dose-dependent manner.^{234,236} Given the recent evidence that serotonin uptake blockers alleviate some of the symptoms associated with psychostimulant "craving," these findings suggest that the effects of noribogaine on the 5-HT transmission may account, in part, for the potential of ibogaine to interrupt drug-seeking behavior in humans. Overall, it may be suggested that the putative efficacy of ibogaine as a pharmacotherapy for cocaine dependence may be attributed to the combined actions of the parent and the metabolite at multiple CNS targets.^{233,239}

6.5.9 Conclusions

Significant advances have been made in understanding the neurochemical consequences of cocaine dependence in the past decade. Integration of the findings observed for cocaine's effects on behavior, together with the identification of the receptors and transporters that undergo compensatory adaptations to neutralize cocaine's effects, has led to the identification of several potential neurochemical targets for the development of cocaine pharmacotherapies. Pharmacotherapies that target one or more of the neurochemical systems that have been altered by protracted cocaine use may alleviate the dysphoria, depression, and anxiety that underlie relapse and compulsive cocaine use.

6.6 NEUROPSYCHIATRIC CONSEQUENCES OF CHRONIC COCAINE ABUSE

Deborah C. Mash, Ph.D.

Departments of Neurology and Molecular and Cellular Pharmacology, University of Miami, Miller School of Medicine, Miami, Florida

Mortality data have indicated that deaths involving psychostimulant drugs stem not only from overdose, but also from drug-induced mental states that may lead to serious injuries.¹ The arrival of inexpensive smokable "crack" cocaine has radically changed the nature of the epidemic and revealed the great addictive potential of cocaine. Cocaine, particularly smoked "crack" cocaine, is known to be one of the most widely abused psychoactive substances in the U.S. With the increased use of cocaine in its various forms over the past 15 years, researchers and clinicians have focused on the definition of cocaine dependence and withdrawal.² Cocaine was not thought to be addictive prior to the 1980s, as neither chronic use nor its cessation resulted in the physiological tolerance

or withdrawal observed in opiate dependence. The progression of occasional use to compulsive use,³ and the description of a cocaine abstinence syndrome,⁴ has led to the definition of diagnostic criteria for cocaine dependence. Clinical experience has fostered the view that persons with psychiatric disorders tend to have high rates of substance abuse, and vice versa.^{5,6} Epidemiological studies demonstrate that a large portion of the population experiences both mental and addictive disorders.⁷ These studies have underscored the gravity of the problem of dual diagnoses of mental health and substance abuse disorders.

6.6.1 Differential Diagnosis of Psychotic Disorders

Drug use is a major complicating factor in psychosis, it renders the management of psychotic disorders more difficult, and adverse reactions to recreational drugs may mimic psychosis.⁸ The differential diagnosis of psychotic disorders in the young routinely includes “drug induced psychosis.” This diagnostic category has not had consistent definition and the relationship between drug use and psychotic symptoms is controversial. Adverse psychiatric effects associated with acute cocaine intoxication include extreme agitation, irritability or affective liability, impaired judgment, paranoia, hallucinations (visual or tactile), and, sometimes, manic excitement. Medical and psychiatric symptoms caused by acute cocaine intoxication are a common reason for presentation to the emergency department. Psychiatric symptoms of cocaine intoxication usually subside within 24 h, but some patients may require benzodiazepines for acute agitation. Neuroleptics are often used for the treatment of unremitting paranoid psychosis, hallucinations, and delusions. The transient paranoid state is a common feature of cocaine dependence, with affected persons possessing an obvious predisposition to this drug-induced state.⁹ Psychiatric complications of cocaine intoxication include cocaine-induced paranoia, agitated delirium, delusional disorder, and the depressed mood and dysphoria associated with abrupt cocaine withdrawal (Table 6.6.1).

Extended behavioral signs of cocaine psychosis usually imply the presence of an underlying major psychopathology in susceptible individuals.⁹ Cocaine-induced psychosis typically manifests as an intense hypervigilance (paranoia) accompanied by marked apprehension and fear. Auditory and tactile hallucinations, formal thought disorder, and ideas of reference frequently noted with chronic use of amphetamines are not prevalent in cocaine abusers. Paranoid experience secondary to cocaine use is usually limited to a drug episode, which dissipates by the time the user awakens from the “crash,” usually about 8 to 36 h after the cessation of the cocaine “binge.”¹⁰ In a sample of 100 cocaine-dependent males, none reported cocaine paranoia extending beyond the crash phase.¹⁰

In contrast to the effects of cocaine, amphetamine has greater and longer-acting psychotogenic properties.¹¹ Angrist¹¹ has suggested that high rates of cocaine use that cause sustained elevations in plasma levels may be necessary for the development or kindling of an episode of cocaine psychosis. In keeping with this suggestion, certain cocaine-induced effects are known to become progressively more intense after repeated administration, a phenomenon referred to as sensitization. However, Satel and co-workers¹⁰ have provided data to suggest that instances of cocaine-induced paranoia or psychosis lasting more than several days most likely indicate the presence of an underlying primary psychotic disorder.

Figure 6.6.1 Tracking the incidence of cocaine overdose deaths in Dade County, FL. Medicolegal investigations of the deaths were conducted by forensic pathologists. Forensic pathologists evaluate the scene environment and circumstances of death and autopsied the victim in order to determine the cause and manner of death. The circumstances of death and toxicology results were reviewed before classifying a death due to cocaine toxicity with or without preterminal delirium. There was a sharp increase in the incidence of cocaine-related and cocaine overdose cases with the arrival of “crack” cocaine in Dade County. The incidence of cocaine delirium victims is shown by year, from the first report in 1982.

6.6.2 Cocaine Delirium

Delirium symptoms suggest dysfunction of multiple brain regions.¹² Clinical subtypes of delirium with unique and definable phenomenological or physical characteristics are not widely accepted. At present, very little information is known about the neuropathogenesis of cocaine delirium. While various neurotransmitter alterations may converge to result in a delirium syndrome or subtype thereof, an excess of the neurotransmitter dopamine (DA) has been implicated as a cause of cocaine delirium.

In 1985, a case series of cocaine overdose victims who died following a syndrome of excited delirium was first described.¹³ It was not clear whether this type of cocaine toxicity represented a new syndrome that was associated with cocaine use alone, or whether there were other causes or underlying genetic risk factors. The cocaine delirium syndrome comprises four components that appear in sequence: hyperthermia, delirium with agitation, respiratory arrest, and death. An episode of cocaine delirium is most often seen at the end of one or more days of drug use.¹⁴ Compared with other accidental cocaine toxicity deaths, a larger proportion of victims of cocaine delirium survive longer after the onset of the overdose. This factor probably accounts for the lower blood cocaine concentrations reported for cocaine delirium victims.¹⁵ The incidence of this disorder is not known with any certainty, but the number of cases has increased markedly since the beginning of the epidemic of “crack” cocaine use in Dade County, FL (Figure 6.6.1).

In the original report of Wetli and Fishbain,¹³ they described the cocaine delirium syndrome in seven cases, and all had somewhat stereotyped histories. A typical example of a cocaine delirium victim was the case of a 33-year-old man, who in an agitated state started pounding on the door of his former house. He was shouting that he wanted to see his wife and daughter. The occupants informed him that nobody by that name resided there; yet he continued. Four bystanders finally restrained him and assisted police units upon their arrival. The subject was handcuffed and put into a police car, whereupon he began to kick out the windows of the vehicle. The police subsequently restrained his ankles and attached the ankle restraints and handcuffs together. He was then transported to a local hospital. While en route, the police officers noted that he became tranquil. Upon

Table 6.6.2 Common Traits Associated with the Fatal Cocaine Delirium Syndrome

Male
Extreme Agitation
Hyperthermia (>103°F)
High body mass index
Survive longer than 1 h after the onset of symptoms
Die in police custody

arrival at the hospital approximately 45 min after the onset of the agitated delirium, the subject was discovered to be in a respiratory arrest.

A post-mortem examination and a rectal temperature of 41°C (106°F) were recorded. He had needle marks typical of intravenous drug abuse and pulmonary and cerebral edema. Abrasions and contusions of the ankles and wrists were evident from his struggling. Lidocaine was not administered to the victim during the resuscitative attempts. The clinical presentation of cocaine delirium is different from that of nonpsychotic cocaine abusers with sudden death or massive drug overdose. The cocaine delirium victims are almost always men, they are more likely to die in custody, and are more likely to survive for more than 1 h after the onset of symptoms (Table 6.6.2).

In the epidemiological tracking of agitated delirium victims in Metropolitan Dade County, men with preterminal delirium comprised approximately 10% of the annual number of cocaine overdose deaths. The demographic trends show that the proportion of these cases remains consistent throughout the epidemic of cocaine abuse and tends to track the annual frequency of cocaine-related sudden deaths. This observation suggests that a certain percentage of cocaine addicts may be at risk for cocaine delirium with chronic abuse.

Cocaine delirium deaths are seasonal and tend to cluster during the late summer months. Core body temperatures are markedly elevated, ranging from 104°C to 108°C. Based on a review of the constellation of psychiatric symptoms associated with this disorder, Kosten and Kleber¹⁶ have termed agitated delirium as a possible cocaine variant of neuroleptic malignant syndrome. Neuroleptic malignant syndrome (NMS) is a highly lethal disorder seen in patients taking dopamine (DA) antagonists or following abrupt withdrawal from DAergic agonists.^{17,18} NMS is usually associated with muscle rigidity, while the cocaine variant of the syndrome presents with brief onset of rigidity immediately prior to respiratory collapse.¹⁹

At present it is not clear whether extreme agitation, delirium, hyperthermia, and rhabdomyolysis are effects of cocaine that occur independently and at random among cocaine users, or whether these features are linked by common toxicologic and pathologic processes.²⁰ Rutenber and colleagues²⁰ have examined excited delirium deaths in a population-based registry of all cocaine-related deaths in Dade County. This study has led to clear description of the cocaine delirium syndrome, its pattern of occurrence in cocaine users over time, and has identified a number of important risk factors for the syndrome.

Cocaine delirium deaths are defined as accidental cocaine toxicity deaths that occurred in individuals who experienced an episode of bizarre behavior prior to death. Bizarre behavior is defined as hyperactivity accompanied by incoherent shouting, aggression (fighting with others or destroying property), or evidence of extreme paranoia as described by witnesses and supported by scene evidence. The results of this study demonstrate that victims are more likely to be male, black and younger than other cocaine overdose toxicity deaths. The most frequent route of administration was injection for the excited delirium victims as compared to inhalation for the other accidental cocaine toxicity deaths. The frequency of smoked "crack" cocaine was similar for both groups. Of the excited delirium victims, 39% died in police custody as compared with only 2% for the comparison group of accidental cocaine toxicity cases.²⁰ A large proportion of these individuals survive between 1 and 12 h after the onset of the syndrome.

The most striking feature of the excited delirium syndrome is the extreme hyperthermia. The epidemiological data²⁰ provide some clues for the etiology of the elevated body temperature. Victims of cocaine excited delirium have higher body mass indices. This finding suggests that muscle mass and adiposity may contribute to the generation of body heat. Temporal clustering in summer months¹³ supports the hypothesis that abnormal thermoregulation is an important risk factor for death in people who develop the syndrome. Being placed in police custody prior to death can also raise body temperature through increased psychomotor activity if the victim struggles in the process of restraint. Descriptions of the circumstances around death suggest that police officers frequently had to forcibly restrain these victims. Positional asphyxia and a restraint-induced increase in catecholamines have been hypothesized as contributing causes of cocaine delirium.²¹

6.6.3 Neurochemical Pathology of Cocaine Delirium

The mesolimbic dopaminergic (DAergic) system is an important pathway mediating reinforcement and addiction to cocaine and other psychostimulants.²² Cocaine potentiates DAergic neurotransmission by binding to the DA transporter and blocking neurotransmitter uptake, leading to marked elevations in synaptic DA (for review, see Reference 23). Long-term cocaine abuse leads to neuroadaptive changes in the signaling proteins that regulate DA homeostasis. DA transporter binding site densities have been shown to be upregulated *in vitro* in the post-mortem brain of cocaine addicts,^{24–27} and *in vivo* in acutely abstinent cocaine-dependent individuals.²⁸

A number of different studies point to a possibility of a defective interaction of cocaine with the DA transporter in the etiology of cocaine delirium. The effects of chronic, intermittent cocaine treatment paradigms on the labeling of the cocaine recognition sites on the DA transporter have been investigated in rat studies. Neuroadaptive changes in the DA transporter have been characterized with a number of different radioligands, including [³H]cocaine, the cocaine congeners [³H]WIN 35,428 and [¹²⁵I]RTI-55, and more recently with [¹²⁵I]RTI-121 (for review, see Reference 29). In contrast to the classic DA transport inhibitors ([³H]mazindol, [³H]GBR 12935, and [³H]nomifensine), the cocaine congeners ([³H]WIN 35,428, [¹²⁵I]RTI-55, and [¹²⁵I]RTI-121) label multiple sites with a pharmacological profile characteristic of the DA transporter in rat, primate, and human brain.^{30–32} Chronic treatment of rats with intermittent doses of cocaine demonstrated a twofold to fivefold increase in the apparent density of [³H]cocaine binding sites in the striatum.³³ Rats that were allowed to self-administer cocaine in a chronic unlimited access paradigm had significant increases in [³H]WIN 35,428 binding sites when the animals were sacrificed on the last day of cocaine access.³⁴ Rabbits treated with cocaine (4 mg/kg i.v. 2 × per day for 22 days) show an elevation in the density of [³H]WIN 35,428 binding sites in the caudate.³⁵ A progression of changes were observed in cocaine self-administering monkeys, which had marked elevations in DA transporter binding sites in the more limbic sectors of the striatum (ventromedial putamen and nucleus accumbens) in monkeys exposed to cocaine for 3 months to 1 year.³⁶ Taken together, these results demonstrate that cocaine exposure leads to an increase in the density of cocaine binding sites on the DA transport carrier.

Cocaine congeners label high- and low-affinity sites on the cloned and native human DA transporter, one of which appears to overlap with the functional state of the carrier protein.³⁷ In cocaine overdose victims, high-affinity cocaine recognition sites on the DA transporter were upregulated significantly in the striatum as compared to age-matched and drug-free control subjects (Figure 6.6.2). If this regulatory change in high affinity [³H]WIN 35,428 binding sites on the human DA transporter reflects an increased ability of the protein to transport DA, it may help to explain the addictive liability of cocaine. In synaptosomes isolated from cryoprotected brain specimens, DA uptake function was elevated twofold in the ventral striatum from cocaine users as compared to age-matched drug-free control subjects.²⁷ In contrast, the levels of [³H]DA uptake were not elevated in victims of excited cocaine delirium, who experienced paranoia and marked agitation prior to death. In keeping with the increase in DA transporter function, radioligand binding

Figure 6.6.2 *In vitro* autoradiographic maps of [3 H]WIN 35,428 labeling of the DA transporter in coronal sections of the striatum. (A) Representative age-matched and drug-free subject, (B) cocaine overdose victim, and (C) cocaine delirium victim. The brain maps illustrate the adaptive increase in DA transporter density over the striatum in the cocaine overdose victim. Note the lack of any apparent elevation for the victim presenting with agitated delirium. Since the DA transporter regulates the synaptic concentration of neurotransmitter, the lack of a compensatory upregulation may result in a DA overflow following a cocaine “binge.” Elevated synaptic DA with repeat exposures may kindle the emergence of the agitated delirium syndrome. Gray scale codes are shown in panel B (black = high densities; gray = intermediate; light gray to white = low densities). Abbreviations: Cd, caudate; NA, nucleus accumbens, Pt, putamen.

to the DA transporter was increased in the cocaine users, but not in the victims of excited delirium. These results demonstrate that long-term cocaine abuse leads to neuroadaptive changes in the signaling proteins that regulate dopamine homeostasis, including elevated DA transporter function and binding sites.

Since cocaine potentiates dopaminergic neurotransmission by binding to DA transporter and blocking reuptake, persisting increases in DA transporter function after cocaine levels have fallen in blood and brain may result in an acute decrease in the intrasynaptic concentration of DA and lower DAergic tone. As the transporter carrier upregulates its apparent density in the nerve terminal to more efficiently transport DA back into the presynaptic nerve terminal, more cocaine will be needed to experience cocaine’s reinforcing effects and euphoria. During acute abstinence from cocaine, enhanced function of the DA transporter could lead to net depletion in synaptic DA. This depletion of DA may serve as a biological substrate for anhedonia, the cardinal feature of cocaine withdrawal symptomatology.

Unlike the results seen in cases of accidental cocaine overdose,²⁴ the density of high-affinity cocaine recognition sites on the DA transporter measured in the striatum from cocaine delirium victims fails to demonstrate a compensatory increase with chronic abuse.²⁷ Since the concentration of synaptic DA is controlled by the reuptake mechanism(s), the lack of compensatory increase in cocaine recognition sites could be the defect in DAergic transmission that explains the paranoia and agitation associated with this syndrome. Paranoia in the context of cocaine abuse is common and several lines of evidence suggest that this phenomenon may be related to the function of the DA transporter protein.³⁸ Genetic differences in the makeup of individuals who abuse cocaine may also underlie some of these differences in susceptibility to the development of adverse neuropsychiatric effects with chronic cocaine abuse, that appear to result from a defective regulation of the DA transporter protein.³⁸ In addition to the adverse neuropsychiatric sequelae, cocaine delirium victims are distinguished from other accidental cocaine overdose deaths by the premorbid occurrence of hyperthermia. Body temperature has a high correlation to a disordered CNS, leading to the loss of thermal regulation. DA receptors are known to play a role in regulating core body temperature. Since hyperthermia is a clinical feature of cocaine delirium, Kosten and Kleber¹⁶ have speculated that death occurred due to a malfunction in DAergic control of thermoregulation. Hypothermia receptors are known to be downregulated by high levels of intrasynaptic DA. Direct

application of intracerebral DA at first lowers body temperature; however, a subsequent “rebound” in body temperature occurs about 1 h after discontinuing this stimulation.^{39,40}

When cocaine is repeatedly administered, DAergic receptor numbers are altered.^{40,41} The likelihood of hyperthermia may be increased with chronic cocaine abuse if the DAergic receptors involved in thermoregulation are undergoing adaptive changes with chronic cocaine exposure. In keeping with this hypothesis, cocaine delirium victims had a different profile of D₂ receptor binding within the thermoregulatory centers of the hypothalamus as compared to cocaine overdose deaths.^{25,42} The density of the D₂ DA receptor subtype in the anterior and preoptic nuclei of the hypothalamus in the cocaine delirium subgroup of cocaine overdose deaths were decreased significantly ($p < 0.05$). These results may be relevant to an understanding of the contribution of selective alterations in D₁ and D₂ receptor subtypes in central DAergic temperature regulation. D₁ and D₂ receptors mediate opposite effects on thermoregulation, with the D₁ receptor mediating a prevailing increase in core body temperature, while the D₂ receptor mediates an opposing decrease in temperature.⁴² Thus, the selective downregulation in the density of the D₂ DAergic receptor subtype within the hypothalamus may explain the loss of temperature regulation in cocaine delirium victims.

6.6.4 Conclusions

Cocaine abuse is associated with neuropsychiatric disorders, including acute psychotic episodes, paranoid states, and delirium. The mechanistic basis of these brain states is not fully known. The advent of new tools from the neurosciences and molecular genetics has led to a proliferation of research approaches aimed at defining the neurobiological consequences of chronic cocaine use. The development of radioligands with high specific activity and selectivity for neurotransmitter carriers and receptor subtypes has made it possible to map and quantify the neurochemical pathology in the brains of cocaine abusers. Since the DA transport carrier is a key regulator of DAergic neurotransmission, alterations in the numbers of these reuptake sites by cocaine may affect the balance in DAergic signaling. Understanding the influence of cocaine's effects on DAergic neurotransmission may shed light on the etiology of neuropsychiatric syndromes associated with cocaine abuse and dependence.

6.7 NEUROBIOLOGY OF 3,4-METHYLENEDIOXYMETHAMPHETAMINE (MDMA, OR “ECSTASY”)

Michael H. Baumann, Ph.D. and Richard B. Rothman, M.D., Ph.D.

Clinical Psychopharmacology Section, Intramural Research Program, National Institute on Drug Abuse, National Institutes of Health, Department of Health and Human Services, Baltimore, Maryland

3,4-Methylenedioxymethamphetamine (MDMA, or “Ecstasy”) is an illicit drug used by young adults who attend “rave” dance parties in the U.S., Europe, and elsewhere. The allure of MDMA is related to its unique psychoactive effects, which include amphetamine-like stimulant actions, coupled with feelings of increased emotional sensitivity and closeness to others.^{1,2} Epidemiological data indicate that MDMA misuse among children and adolescents is widespread in the U.S.^{3,4} In a recent sampling of high school students, 10% of 12th graders reported using MDMA at least once.⁵ As shown in Figure 6.7.1, MDMA-related emergency room visits have risen more than 20-fold in recent years, consistent with the increasing popularity of the drug. Serious adverse effects of acute MDMA intoxication include cardiac arrhythmias, hypertension, hyperthermia, serotonin (5-HT) syndrome, hyponatremia, liver problems, seizures, coma and, in rare cases, death.⁶ Accumulating evidence indicates that long-term MDMA abuse is associated with cognitive impairments and mood disturbances, which can last for months after cessation of drug intake.^{7,8}

Despite the potential risks associated with illicit MDMA use, a growing number of clinicians believe the drug could have therapeutic potential in the treatment of psychiatric disorders.⁹ For example, adjunct therapy with MDMA might prove useful for alleviating the anxiety that accompanies post-traumatic stress disorder (PTSD) or end-stage terminal illness. Indeed, clinical trials aimed at testing the efficacy of MDMA for the treatment of PTSD are under way.¹⁰ MDMA has been administered to human subjects in controlled research settings, and few side effects are

Figure 6.7.1 Emergency department mentions of MDMA from 1994–2002. (Adapted from Office of Applied Studies, SAMSHA, Drug Abuse Warning Network, 2002; updated 03/2003.)

observed under these conditions, supporting the relative safety of the drug.^{11,12} The aforementioned considerations provide compelling reasons to evaluate the neurobiology of MDMA and related compounds. In this chapter, we review the acute and long-term effects of MDMA administration on central nervous system (CNS) function. The chapter focuses on results obtained from rats since most preclinical MDMA research has been carried out in this animal model. Experimental data from our laboratory at NIDA are included to supplement literature reports, and clinical data are mentioned in certain instances to note similarities or differences between rats and humans.

6.7.1 MDMA Interacts with Monoamine Transporters

6.7.1.1 *In Vitro* Studies

Figure 6.7.2 shows that MDMA is a ring-substituted analogue of methamphetamine, and “Ecstasy” tablets ingested by humans contain a racemic mixture of (+) and (–) isomers of the drug.^{13,14} Upon systemic administration, MDMA is *N*-demethylated via first-pass metabolism in the liver to yield (+) and (–) isomers of the amphetamine analogue, 3,4-methylenedioxymphetamine (MDA).^{15,16} Initial pharmacological studies carried out in the 1980s revealed that isomers of MDMA and MDA stimulate efflux of 5-HT, and to a lesser extent dopamine (DA), in brain tissue preparations.^{17–19} Subsequent investigations demonstrated that MDMA is a substrate for

Figure 6.7.2 Chemical structures of MDMA and related compounds.

Figure 6.7.3 Dose–response effects of MDMA on the release of preloaded [³H]5-HT (left panel) and [³H]DA (right panel) from synaptosomes *in vitro*. [³H]Transmitter release is expressed as percent of tritium retained in tissue. Various concentrations of MDMA were incubated with or without the 5-HT uptake blocker fluoxetine (10 nM) in [³H]5-HT assays, whereas various concentrations of MDMA were incubated with or without the DA uptake blocker GBR12909 (10 nM) in [³H]DA assays. Data are mean \pm SD for three separate experiments, each performed in triplicate. See Baumann et al.³⁹ for methods.

monoamine transporter proteins, evoking the non-exocytotic release of 5-HT, DA, and norepinephrine (NE) from nerve terminals.^{20–22}

Like other substrate-type releasers, MDMA and MDA bind to plasma membrane monoamine transporters and are subsequently translocated into the cytoplasm.²³ The ensuing transmitter release occurs by a two-pronged mechanism: (1) transmitter molecules exit the cell along their concentration gradient via a diffusion-exchange process that involves reversal of normal transporter flux, and (2) cytoplasmic concentrations of transmitter are increased due to drug-induced disruption of vesicular storage.^{24,25} This latter action serves to markedly increase the pool of cytoplasmic transmitter available for diffusion-exchange release. Because substrate-type releasing drugs must be transported into cells to promote transmitter release, transporter uptake inhibitors can block the effects of releasers. Figure 6.7.3 depicts data from our laboratory showing MDMA produces a dose-dependent release of preloaded [³H]5-HT and [³H]DA from rat brain synaptosomes. In these experiments, the “release” of preloaded radiolabeled transmitter is expressed as a reduction in the amount of tritium retained in tissue. Reserpine is added to the incubation medium to prevent the trapping of radiolabeled transmitter in vesicles.^{26,27} MDMA-induced release of [³H]5-HT is antagonized by co-incubation with the selective 5-HT uptake inhibitor fluoxetine, whereas release of [³H]DA is antagonized by the selective DA uptake inhibitor GRB12909. These findings support the hypothesis that MDMA stimulates 5-HT and DA release *in vitro* via interactions at 5-HT transporters (SERT) and DA transporters (DAT), respectively.

The data in Table 6.7.1 summarize structure–activity relationships for MDMA, MDA, and related drugs, with respect to monoamine release from rat brain synaptosomes.^{28,29} Stereoisomers of MDMA and MDA are substrates for SERT, DAT, and NE transporters (NET), with (+) isomers exhibiting greater potency as releasers. In particular, (+) isomers of MDMA and MDA are much more effective DA releasers than their corresponding (–) isomers. It is noteworthy that (+) isomers of MDMA and MDA are rather nonselective in their ability to stimulate monoamine release *in vitro*. When compared to other amphetamines, the major effect of methylenedioxy ring-substitution is enhanced potency for 5-HT release and reduced potency for DA release. For example, (+)-MDMA releases 5-HT ($EC_{50} = 70.8$ nM) about ten times more potently than (+)-methamphetamine ($EC_{50} = 736$ nM), whereas (+)-MDMA releases DA ($EC_{50} = 142$ nM) about six times less potently than (+)-methamphetamine ($EC_{50} = 24$ nM).

Table 6.7.1 Profile of MDMA and Related Compounds as Monoamine Transporter Substrates

Drug	5-HT Release EC ₅₀ (nM ± SD)	NE Release EC ₅₀ (nM ± SD)	DA Release EC ₅₀ (nM ± SD)
(+)-Methamphetamine	736 ± 45	12 ± 0.7	24 ± 2
(-)-Methamphetamine	4640 ± 240	29 ± 3	416 ± 20
(±)-MDMA	74.3 ± 5.6	136 ± 17	278 ± 12
(+)-MDMA	70.8 ± 5.2	110 ± 16	142 ± 6
(-)-MDMA	337 ± 34	564 ± 60	3682 ± 178
(+)-Amphetamine	1765 ± 94	7.1 ± 1.0	25 ± 4
(±)-MDA	159 ± 12	108 ± 12	290 ± 10
(+)-MDA	99.6 ± 7.4	98.5 ± 6.1	50.0 ± 8.0
(-)-MDA	313 ± 21	287 ± 23	900 ± 49

6.7.1.2 In Vivo Microdialysis Studies

The technique of *in vivo* microdialysis allows continuous sampling of extracellular fluid from intact brain, and dialysate samples can be assayed for monoamine transmitters using various analytical methods.³⁰ Microdialysis studies in rats demonstrate that systemic administration of MDMA increases extracellular levels of 5-HT and DA in the brain, consistent with the *in vitro* results noted above.^{31–34} Pretreatment with 5-HT uptake inhibitors can block the rise in dialysate 5-HT produced by MDMA, suggesting the involvement of SERT.^{33,35} Interestingly, the effect of MDMA administration on dialysate DA appears to be more complex and entails at least two processes: (1) a tetrodotoxin-insensitive mechanism that involves substrate interaction at DAT proteins,^{36,37} and (2) a tetrodotoxin-sensitive mechanism that involves activation of 5-HT_{2A} receptor sites by endogenous 5-HT.^{33,38} Findings from our laboratory, illustrated in Figure 6.7.4, reveal that intravenous (i.v.) MDMA administration causes dose-related elevations in extracellular levels of 5-HT and DA in rat nucleus accumbens.³⁹ In these experiments, drugs were administered to conscious rats undergoing *in vivo* microdialysis. Dialysate levels of 5-HT and DA were determined by high-performance liquid chromatography coupled to electrochemical detection (HPLC-ECD). We found

Figure 6.7.4 Dose–response effects of MDMA on extracellular levels of endogenous 5-HT (left panel) and DA (right panel) in rat nucleus accumbens. Male rats undergoing *in vivo* microdialysis received i.v. injections of 1 and 3 mg/kg MDMA at 0 and 60 min, respectively. Dialysate levels of 5-HT and DA were assayed by HPLC-ECD. Data are mean ± SEM, expressed as pg/5 µl sample, for *N* = 6 rats/ group. Baseline levels of 5-HT and DA were 0.22 ± 0.03 and 1.44 ± 0.24 pg/5 µl, respectively. *Significant with respect to pre-injection control (*P* < 0.05 Duncan's). See Baumann et al.³⁹ for methods.

that MDMA has greater effects on *in vivo* 5-HT release when compared to DA release, and this observation has been confirmed in brain regions such as cortex and striatum. At the 1 mg/kg i.v. dose of MDMA, extracellular 5-HT was elevated approximately sixfold above baseline whereas extracellular DA was elevated approximately twofold.

6.7.2 Acute Effects of MDMA

6.7.2.1 *In Vivo* Pharmacological Effects of MDMA

The acute CNS effects of MDMA administration are mediated by the release of monoamine transmitters, with the subsequent activation of presynaptic and postsynaptic receptor sites.⁴⁰ As specific examples in rats, MDMA suppresses 5-HT cell firing, evokes neuroendocrine secretion, and stimulates locomotor activity. MDMA-induced suppression of 5-HT cell firing in the dorsal and median raphe involves activation of presynaptic 5-HT_{1A} autoreceptors by endogenous 5-HT.^{41,42} Neuroendocrine effects of MDMA include secretion of prolactin from the anterior pituitary and corticosterone from the adrenal glands.⁴³ Evidence supports the notion that these MDMA-induced hormonal effects are mediated via postsynaptic 5-HT₂ receptors in the hypothalamus, which are activated by released 5-HT. MDMA elicits a unique profile of locomotor effects characterized by forward locomotion and elements of the 5-HT behavioral syndrome such as flattened body posture, Straub tail, and forepaw treading.^{44–46} The complex motor effects of MDMA are dependent on monoamine release followed by activation of multiple postsynaptic 5-HT and DA receptor subtypes in the brain,⁴⁷ but the precise role of specific receptor subtypes is still under investigation.

In our laboratory, we carried out *in vivo* microdialysis in rats that were housed in chambers equipped with photo-beams to allow automated assessment of motor activity. Under these conditions, i.v. MDMA administration increases motor activity in conjunction with elevations in extracellular 5-HT and DA (see Figure 6.7.4). The data in Figure 6.7.5 demonstrate that MDMA increases forward locomotion (i.e., ambulation) and repetitive movements (i.e., stereotypy) in a dose-dependent fashion. Stereotypy produced by i.v. MDMA consists predominately of lateral side-to-side head weaving and reciprocal forepaw treading. We discovered that MDMA-induced 5-HT release in the nucleus accumbens and caudate nucleus is significantly correlated with stereotypic movements, whereas DA release in these brain regions is correlated with ambulation. These data suggest

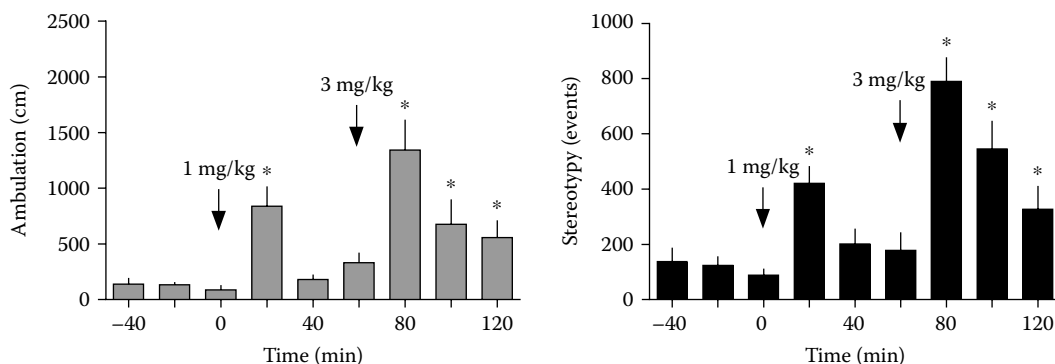

Figure 6.7.5 Dose–response effects of MDMA on ambulation (left panel) and stereotypy (right panel) in rats undergoing *in vivo* microdialysis. Male rats received i.v. injections of 1 and 3 mg/kg MDMA at 0 and 60 min, respectively. Ambulation (i.e., forward locomotion) and stereotypy (i.e., repetitive movements) were measured by photo-beam break analysis. Data are mean \pm SEM, expressed as centimeters traveled for ambulation and number of events for stereotypy, with $N = 6$ rats/group. *Significant with respect to pre-injection control ($P < 0.05$ Duncan's). See Baumann et al.³⁹ for methods.

that 5-HT and DA systems influence MDMA-induced motor activation in a region-specific and modality-specific manner.

Adverse effects of high-dose MDMA intoxication, including cardiovascular stimulation and elevated body temperature, are thought to involve monoamine release from sympathetic nerves in the periphery or nerve terminals in the CNS.⁴⁸ MDMA increases heart rate and mean arterial pressure in conscious rats;^{49,50} this cardiovascular stimulation is probably related to MDMA-induced release of peripheral NE stores, similar to the effects of amphetamine.⁵¹ MDMA is reported to have weak agonist actions (i.e., $IC_{50} > 1 \mu M$) at α_2 -adrenoreceptors and 5-HT₂ receptors, which might influence its cardiac and pressor effects.^{52–54} Moreover, the MDMA metabolite MDA is a potent 5-HT_{2B} agonist, and this property could contribute to adverse cardiovascular effects.²⁹ The ability of MDMA to elevate body temperature is well characterized in rats,^{35,43,46,55} and this response has long been considered a 5-HT-mediated process. However, a recent study by Mechan et al.³⁵ provides convincing evidence that MDMA-induced hyperthermia in rats involves activation of postsynaptic D₁ receptors by released DA.

6.7.2.2 MDMA Metabolism

MDMA is extensively metabolized in humans and other species.⁵⁶ Figure 6.7.6 depicts the major pathway of MDMA biotransformation in humans, which entails: (1) *O*-demethylation catalyzed by cytochrome P450 2D6 (CYP2D6) and (2) *O*-methylation catalyzed by catechol-*O*-methyltransferase (COMT). CYP2D6 and COMT are both polymorphic in humans; the differential expression of CYP2D6 isoforms leads to marked inter-individual variations in the metabolism of serotonergic medications (e.g., SSRIs).⁵⁷ Interestingly, CYP2D6 is not present in rats, and this species expresses a homologous but functionally distinct cytochrome P450 2D1 that metabolizes MDMA.^{58,59} A minor pathway of MDMA biotransformation in humans involves *N*-demethylation

Figure 6.7.6 Metabolism of MDMA in humans. Abbreviations: CYP2D6, cytochrome P450 2D6; CYP3A4, cytochrome P450 3A4; COMT, catechol-*O*-methyltransferase. (Adapted from de la Torre and co-workers.⁵⁶)

of MDMA to form MDA, which is subsequently *O*-demethylenated and *O*-methylated as described above. The *N*-demethylation pathway represents a more important mechanism for biotransformation of MDMA in rats when compared to humans.⁶⁰

As noted above, MDA is a potent stimulator of monoamine release (see Table 6.7.1), and recent reports indicate that a number of MDMA metabolites are bioactive. For example, Forsling et al.⁶¹ showed that the metabolite 4-hydroxy-3-methoxymethamphetamine (HMMA) is more potent than MDMA as a stimulator of vasopressin secretion from rat posterior pituitaries *in vitro*. The neuroendocrine effects produced by *in vivo* administration of MDMA metabolites have not been examined. Monks et al.⁶² demonstrated that catechol metabolites of MDMA and MDA, namely, 3,4-dihydroxymethamphetamine (HHMA) and 3,4-dihydroxyamphetamine (HHA), exhibit neurotoxic properties when oxidized and conjugated with glutathione. Further characterization of the biological effects of MDMA metabolites is an important area of research.
